FIG. 7—VARIATION WITH "t_0" OF THE INVERSE TIME CONSTANT "α" OF EACH EXPONENTIAL

Accuracy of the Method

It has been stated that the resolution of a current-time relation into three exponentials is quite indeterminate. The constants of the three exponentials depend entirely on the value of time t_0, of the empirical discharge current-time relation, at which the first tangent is drawn. Fig. 6 illustrates the point for the current-time relation of Fig. 4 showing the first tangent drawn at two different values of t_0 with the shaded areas indicating in each case the neglected portions of the curve.

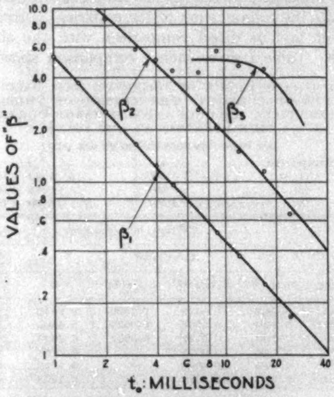

FIG. 8—VARIATION WITH "t_0" OF THE CONSTANT MULTIPLIER "β" OF EACH EXPONENTIAL.

Figs. 7, 8 and 9 give respectively for each exponential the variation with t_0 of the inverse time constant α, the constant multiplier β, and their ratio β/α. This ratio is shown in Fig. 5 to be a measure of the maximum contributions to the in-phase and quadrature components with varying frequency. Figs. 7 and 8 are significant in pointing out the definite dependence of the α and β constants on the chosen value of t_0, while their ratio, as shown by Fig. 9, is found to be essentially independent of t_0 at least for the first and second exponentials. The upper curve of this figure gives the summation of the three ratios, which is seen to be independent of t_0. From Fig. 5 and the equation (10) for the apparent capacitance it follows that this summation gives a measure of the dielectric constant at zero frequency, ϵ_1, in terms of the geometric dielectric constant, ϵ_0, at infinite frequency. Specifically, the relation is

$$\frac{\epsilon_1 - \epsilon_0}{\epsilon_0} = \frac{\beta_1}{\alpha_1} + \frac{\beta_2}{\alpha_2} + \frac{\beta_3}{\alpha_3} \qquad (14)$$

That this summation should prove independent of t_0 further corroborates the sufficiency of three exponentials.

While the constants of the three exponentials are definitely functions of t_0, the total contribution to the a-c. behavior, as given by the in-phase and quadrature components of current at a given voltage and frequency, is essentially independent of t_0 for a limited range of values. This is illustrated in Figs. 10 and 11 which show that for t_0 beyond six milliseconds the in-phase and quadrature components are essentially constant even though the separate contributions of each exponential may vary widely. This is particularly true of the in-phase component, Fig. 10, which is a measure of the power factor, and therefore the one most readily checked by experiment. No physical significance is to be attached to the actual numerical values of the constants of the three exponentials. They serve merely as an empirical means of computing the a-c. behavior. It is apparent from Fig. 10 that the optimum value of t_0 lies in the neighborhood of the period of the alternating wave thus corroborating from another point of view the criterion of what constitutes suitable d-c. measurements.

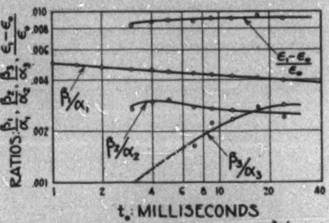

FIG. 9—VARIATION WITH "t_0" OF THE RATIOS β_1/α_1, β_2/α_2, β_3/α_3, AND THEIR SUMMATION, $(\epsilon_1-\epsilon_0)/\epsilon_0$

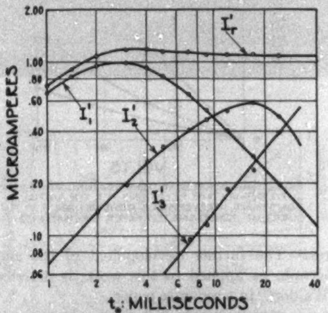

FIG. 10—CONTRIBUTION OF REVERSIBLE ABSORPTION AT 1500 VOLTS, 60 CYCLES. VARIATION WITH "t_0" OF THE IN PHASE COMPONENT OF CURRENT (I'_r) SHOWING THE CONTRIBUTIONS OF EACH EXPONENTIAL.

IRREVERSIBLE CONDUCTION

The irreversible conduction current as observed under continuous potential with the amplifier oscillograph for some of the cable oils tested is characterized by an initial current which remains constant for approximately one second and then decays with time until it merges into the final conductivity. This initial constant current, when it obeys Ohm's law, gives directly the value of the in-phase component of current at the same effective voltage. See Whitehead,[11] "The Conductivity of Insulating Oils, II" for a complete account of this initial conductivity.

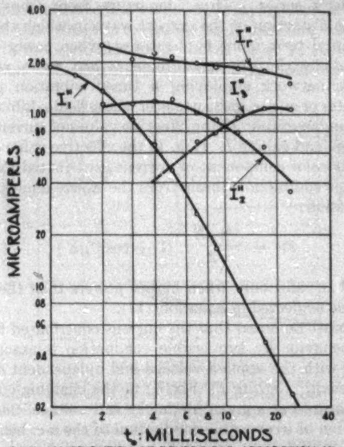

FIG. 11—CONTRIBUTION OF REVERSIBLE ABSORPTION AT 1500 VOLTS, 60 CYCLES. VARIATION WITH "t_0" OF THE QUADRATURE COMPONENT OF CURRENT (I''_r) SHOWING THE CONTRIBUTIONS OF EACH EXPONENTIAL.

In some of the impregnated paper specimens tested the irreversible conduction current does not obey Ohm's law, although it is still characterized by an initial constant conductivity. In such cases the irreversible constant current increases faster than the voltage as illustrated by the typical example shown in Fig. 12. For analytical purposes express the observed current-voltage relation by means of the power series:

$$i(e) = ae + be^3 + ce^5 + \ . \ . \ . \qquad (15)$$

in which the coefficients may be directly determined from the observed current-voltage relation. To facilitate this, however, express the above relation thus:

$$i(e) = \gamma \sinh \mu e \qquad (16)$$

where the γ and μ constants are chosen to give the best agreement with the observed curve within the voltage range required. Obviously μ is a function of the temperature alone while γ is a function of the temperature and the dimensions of the capacitor. Expand equation (**16**) into a series

$$i(e) = \gamma \left[\mu e + \frac{(\mu e)^3}{3!} + \frac{(\mu e)^5}{5!} + \ldots \right] \qquad \textbf{(17)}$$

in which higher powers than the fifth may be neglected.

To obtain the current-time relation for the alternating case substitute for the value of e in equation (**17**) its expression as a periodic sinusoidal function of time. This results in a power series of sin α, where $\alpha = (\omega t + \theta)$, in which all the higher powers of sinα may be broken up into harmonic components by means of Fourier's series. Thus, departure from Ohm's law causes distortion of the current wave in which the fundamental term alone is of interest, when power factor and dielectric loss measurements are made with a bridge network employing a tuned vibration galvanometer or an a-c. galvanometer whose field exhibits only the fundamental. Using effective values of current and voltage and calling I_i' (Fig. 1) the effective value of the *fundamental* component of current contributed by irreversible conduction obtain from the above analysis the expression:

$$I_i' = \frac{\gamma \mu E}{2} \left[1 + \cosh \mu E \right] \qquad \textbf{(18)}$$

which is valid only when higher powers than the fifth may be neglected in equation (**17**).

It must be noted that the current contributed to the a-c. behavior by irreversible conduction is exactly in phase with the applied voltage and independent of the frequency. Letting I'' (Fig. 1) be the charging current as measured at a given frequency and voltage, the contribution of irreversible conduction to the a-c. behavior is as follows:

$$\left. \begin{array}{ll} \text{Phase defect angle } \tan \Psi_i = \dfrac{I_i'}{I''} & \\ & \\ \text{Irreversible loss} \qquad W_i = E I_i' & \end{array} \right\} \qquad \textbf{(19)}$$

where I_i' is given directly by the initial constant current under continuous potential when Ohm's law is obeyed or is computed by (**18**) when the non-linear current-voltage relation is determined according to equation (**17**). Table II gives the computed variation of power factor with voltage and temperature for the typical example shown in Fig. 12.

60	50.8	0.00072	0.00082	0.00090	0.00104

EXPERIMENTAL PROCEDURE

Continuous potential measurements and corresponding 60-cycle a-c. measurements were made on a number of samples of oil, paper, and impregnated paper at voltages of 500, 1,000, and 1,500, and at temperatures of 30, 45, and 60 deg. cent. For a complete description of the constant temperature, drying, impregnating, and measuring tanks and of the test specimens see Whitehead and Kouwenhoven,[12] "Fundamental Properties of Impregnated Paper."

The measurements under continuous voltage include the determination of the charge and discharge current-time relations with the aid of the amplifier-oscillograph. The amplifier increases the normal sensitivity of the electromagnetic oscillograph 10^5 times, giving a deflection on the photographic film of 1 mm. per 4×10^{-8} amperes. The further development of the amplifier oscillograph, as applied to this work, is described by S. K. Waldorf[13] in a separate paper.

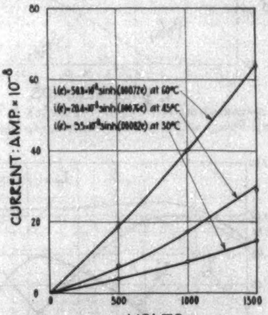

FIG. 12—VARIATION WITH TEMPERATURE OF CURRENT-VOLTAGE RELATIONS FOR THE INITIAL, CONSTANT, IRREVERSIBLE CONDUCTION CURRENT IMPREGNATED PAPER SPECIMEN C7.

The a-c. measurements include the determination of power factor and apparent capacitance using a modified Schering bridge whose power factor sensitivity is $\pm 5 \times 10^{-6}$. The development, theory, and special features of this bridge are described in a separate paper by Kouwenhoven and Baños.[14]

EXPERIMENTAL RESULTS

Paper Specimens. Dry paper specimens reveal a dielectric loss due entirely to reversible absorption; that is, the irreversible conduction current is not measurable as shown by the equality of charge and discharge currents in Fig. 2. Fig. 13 gives a typical pair of oscillograms at a given temperature and voltage. From such oscillograms are computed the current-time relations shown in Figs. 14 and 15 which illustrate the respective variations with voltage and temperature. The insert in Fig. 14 shows how closely Curie's law is obeyed, while the insert in Fig. 15 illustrates the variation of the current ordinates with temperature.

Table III gives the variation with temperature of the α and β constants of the absorption current-time relation for the dry paper specimen before and after impregnation with an oil whose electrical characteristics are described in the next section. Interesting changes of the constants are noted as result of impregnation. These differences are best appreciated by direct comparison of Figs. 2 and 3. Table IV gives the correlation of a-c. and d-c. measurements for the whole range of temperature and voltage explored. Note that in general the agreement between computed and measured losses is very close.

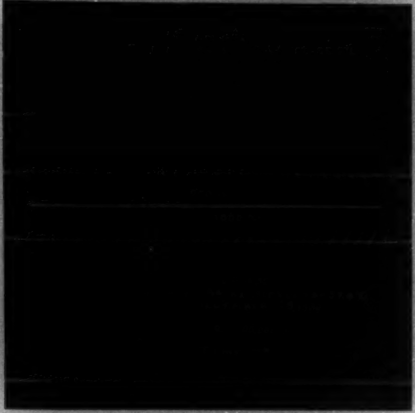

Fig. 13

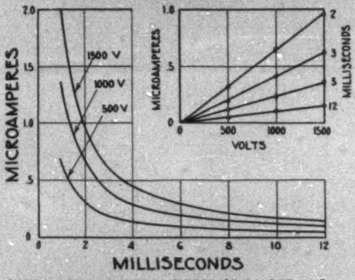

FIG. 14 – VARIATION WITH VOLTAGE OF CHARGE AND DISCHARGE CURRENT-TIME RELATIONS AT 60°C DRY PAPER SPECIMEN A7.

Oil Specimens. Fig. 16 gives a set of typical charge oscillograms at 1,500 volts and at 30, 45, and 60 deg. cent. for the cable oil used to impregnate the above paper specimen. It is noted that the charge current is characterized by a large initial constant current which accounts for the major part of the loss. Superimposed on this initial current is a smaller decaying current function of time which is reversible and, therefore, attributable to dielectric absorption in oil. Fig. 18 shows the variation with temperature of the charge and discharge current-time relations at 1,500 volts. The equations for discharge show that the small element of dielectric absorption is expressible by a single exponential thus corroborating the results published by Whitehead[11] in "The Conductivity of Insulating Oils, II." Fig. 17 gives the evidence that the initial constant current in the insulating oils tested obeys Ohm's law.

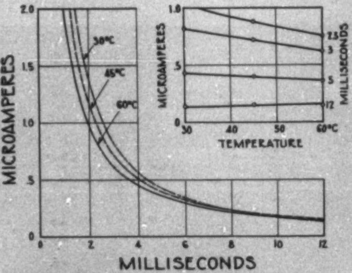

FIG. 15 – VARIATION WITH TEMPERATURE OF CHARGE AND DISCHARGE CURRENT-TIME RELATIONS AT 1500 VOLTS. DRY PAPER SPECIMEN A7.

Table V gives the comparison between several measured and corresponding computed losses for one oil specimen B-7. The data are typical and the close agreement shown is further evidence of the soundness of the method used in computing the a-c. behavior.

Impregnated Paper Specimens. Some of the changes brought about on a dry paper specimen by impregnation with an insulating oil have already been pointed out in Fig. 3 and Table III. Fig. 3 shows the effect of the conductivity of the insulating oil in increasing the absorption and changing its character. Fig. 19 gives a typical pair of oscillograms in which the presence of the irreversible conduction current is apparent in the charge record. This fact is better appreciated from the equa-

tions of charge and discharge given in Fig. 20, where the irreversible conduction current is seen to be the *constant* difference between charge and discharge currents. This constant irreversible conduction current does not obey Ohm's law, as shown by Fig. 12, and its contribution to the power factor has already been computed from theoretical considerations and given in Table II.

Summary of Specimens. As an example of the insight afforded by this method of analysis, Fig. 21 gives the power factor as a function of temperature for the oil, paper, and impregnated paper specimens. The shaded areas represent the total increase in power factor with impregnation. Through the analysis of the discharge current-time relations it is possible to resolve this increase into two components:

1. The increase in reversible absorption brought about by impregnation.

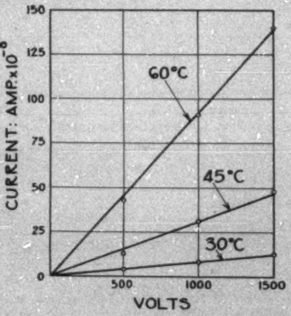

FIG.17—VARIATION OF INITIAL CONSTANT CURRENT WITH VOLTAGE. OIL SPECIMEN B7.

2. The creation of the additional contribution of irreversible conduction totally absent before impregnation and directly attributable to the conductivity of the impregnating oil.

port has made possible the active prosecution of a research on the properties of impregnated paper from which the experimental results here reported have been taken. The authors also wish to acknowledge the interest and careful work of Dr. S. K. Waldorf in the development and operation of the amplifier oscillograph.

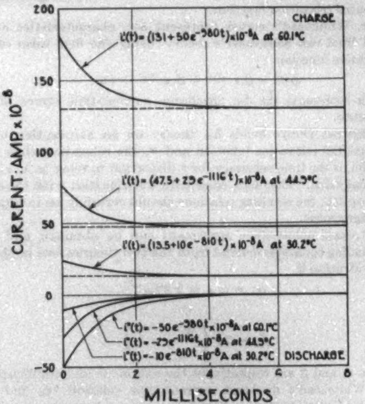

FIG. 18—VARIATION WITH TEMPERATURE OF CHARGE AND DISCHARGE CURRENT-TIME RELATIONS AT 1500 VOLTS. OIL SPECIMEN B7.

CONCLUSIONS

1. It is shown that for any type of dielectric the loss, power factor and capacity at 60 cycles may be accurately predicted from the charge and discharge currents under continuous potential.

2. The method developed is available at any frequency, provided that the continuous potential charge

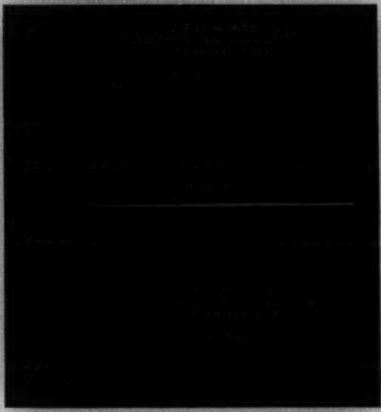

FIG. 19

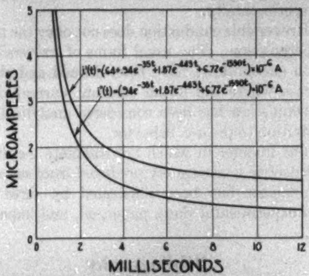

FIG. 20—CHARGE i'(t) AND DISCHARGE i''(t) CURRENT-TIME RELATIONS AT 1500 VOLTS, 60°C. IMPREGNATED PAPER SPECIMEN C7.

and discharge currents may be measured over initial time intervals comparable with the alternating period.

3. The nature of the relaxation function characteristic of reversible absorption in dielectric has been discussed from the experimental and analytical points of view.

4. It has been shown that agreement of the relaxation function with the t^{-n} expression is not general, but on the contrary it is confined to dielectrics showing negligible or no irreversible conduction. The inadequacy of the t^{-n} expression has been proved on experimental and analytical reasons. Chief among them is the failure of the t^{-n} expression to predict accurately the variation of dielectric loss with frequency.

5. The method of three exponentials has been developed as a convenient and sufficient expression for the relaxation function. The sufficiency and accuracy of three exponentials has been proved both analytically and experimentally.

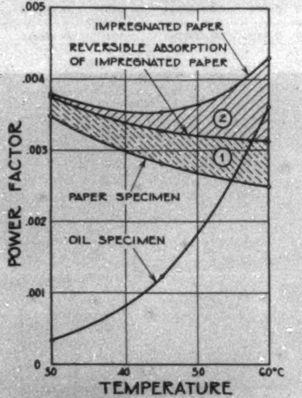

FIG. 21—ANALYSIS OF POWER FACTOR AT 1500 VOLTS. IMPREGNATED PAPER SPECIMEN C7

Increase in Power Factor with Impregnation
(1) Increase in Reversible Absorption
(2) Contribution of Irreversible Conduction

6. Irreversible conduction does not obey the principle of superposition. The usual forms of irreversible conduction encountered have been defined and classified. The case where the initial constant current does not obey Ohm's law has been considered analytically in its contribution to the a-c. behavior.

7. The manner in which the complete a-c. behavior of a dielectric is accurately predicted from suitable d-c. measurements has been illustrated by three typical sets of experimental data, paper, oil, and impregnated paper.

Discussion

H. H. Race: The authors of this paper have presented some very interesting data but they suggest no physical explanation of their results. Therefore Fig. 5 interested me particularly because the variations of capacitance and loss with frequency are similar to corresponding curves calculated using a very definite physical picture, namely, Debye's theory of polar molecules. A comparison of these two separate lines of mathematical thinking, which lead to qualitatively similar results, shows that a correspondence should be expected since both are based upon an exponential relaxation function.

Dr. Whitehead's curves represent a-c. characteristics calculated from von Schweidler's theory using the first term of the relaxation function

$$\phi(t) = \beta_1 \epsilon^{-\alpha_1 t} + \beta_2 \epsilon^{-\alpha_2 t} + \text{etc.}$$

which represents the d-c. discharge current-time curve of the dielectric.

Likewise, Debye builds his theory on an assumption of an exponential relaxation function and τ, the relaxation time used by him, is the time necessary for a distortion to relax to $1/\epsilon$ of its original value. Therefore, since both theories start with the same assumption, the resulting relations should certainly be in qualitative agreement.

An exact quantitative agreement can be obtained and corresponding equations derived from the two theories can be shown to be identical if

$$\alpha_1 = \omega_m = 2\pi f_m \qquad (1)$$

and

$$\beta_1 = \alpha_1 \left(\frac{\epsilon_0}{\epsilon_\infty} - 1 \right) \qquad (2)$$

where α and β are respectively the exponent and coefficient in Dr. Whitehead's discharge current-time relation. ϵ_0 and ϵ_∞ are the measured effective dielectric constants at zero and infinite frequency and f_m is the frequency at which the maximum a-c. loss occurs.

Equation (1) can also be derived from Dr. Whitehead's work by setting $dB(w)/dw = 0$ in equation (11) in order to determine the frequency at which the maximum a-c. loss will occur. Dr. Whitehead has made this calculation and concludes that "only the exponentials with values of α in the neighborhood of (w) at the frequency at which correlation is intended contribute an appreciable amount to the loss component $B(w)$."

Since equation (1) also relates a-c. dielectric losses resulting from the relaxation of polar orientation to d-c. current-time curves resulting from the same relaxation, it seems that the following more general conclusions can be reached.

1. Any mechanism causing an exponential current-time discharge curve after the removal of a constant potential, will also cause an a-c. dielectric loss-frequency curve having a maximum at $f_m = (\alpha/2\pi)$.

2. Inversely, if a maximum is observed in the a-c. loss-frequency curve, the exponent of a d-c. current time curve taken for the same material will be given by this same relation.

3. Conversely, if in a given range of frequency or relaxation time, one of these effects is not found the other will also be absent.

4. Through these relations, a correlation should be possible between Dr. Whitehead's d-c. and 60-cycle measurements and our high frequency data. However, for the mineral oils in which we have measured the dielectric loss, as a function of frequency, we have found no maxima at frequencies less than 10^4 cycles per second, even in high viscosity oils at temperatures as low as 0 deg. cent. Therefore, the d-c. relaxation curves corresponding to the maxima which we have observed should have become negligible in less than 1×10^{-3} second, which is the time at which Dr. Whitehead's measurements begin.

To check the above conclusions and obtain a better comparison between a-c. and d-c. measurements Dr. Whitehead has very kindly furnished us with a sample of his B-7 oil and we hope to present a paper in the near future containing the reasons leading to equation (1) and data on B-7 oil over a wide range of frequency and temperature.

F. M. Clark: In connection with the paper presented by Dr. Whitehead, it is interesting to note the procedure developed a few years ago in the Pittsfield Works Laboratory of the General Electric Company for the gaging of capacitor characteristics. With 5-kva. oil-filled capacitors designed for a-c. voltage application, ranging from 440 to 2,300, it was found that the relative a-c. characteristics could be successfully determined from the so-called "d-c. leakage." In determining this value, the capacitors were charged under d-c. voltage to the desired value, disconnected from the source of supply and allowed to stand under controlled conditions for a period ranging from one to several days, after which the remaining charge was measured. The difference between the original and final charge was used in gaging the a-c. characteristics of the capacitors. This so-called "d-c. leakage" appeared to be of greater value than insulation resistance measurements, probably because the time used to determine the latter was not of sufficient duration. The work was not carried sufficiently far to predict successfully the power factor from the leakage results obtained. With further investigation, it is believed this could be done.

W. A. Del Mar: The practical control of power factor of impregnated paper now lies with the paper tests. In 1922* the control was essentially a matter of oil resistivity.

The change occurred when we changed our paper from Manila to wood pulp and our oil from petrolatum to cylinder oil. The practical problem has long since been solved, but it would be interesting to have the authors explain these facts in the light of their admirably developed theories.

Breakdown of Glass with Alternating Potentials

BY N. D. KENNEY,[1] A. M. LUERY,[1] and J. D. MORIATY[1]
Non-member Non-member Non-member

Synopsis.—*Previous tests on the breakdown of glass with direct potentials indicated the existence of three different regions of breakdown. The present paper describes similar tests on alternating potentials. The following conclusions are reached:*

1. Three distinct regions of breakdown are obtained on alternating current as well as on direct current.

2. In the disruptive and intermediate regions, breakdown occurs at an alternating peak voltage approximately equal to the direct breakdown voltage.

3. In the thermal region, breakdown occurs at an alternating peak voltage somewhat lower than the direct breakdown voltage.

* * * * *

INTRODUCTION

The cause and reason for breakdown of solid dielectrics has resulted in the setting forth of many theories based on both experimental and mathematical research. Research by Kármán, Rogowski and Fock resulted in the establishing of the thermal breakdown theory. Inge and Walther, in their investigations of the breakdown of glass in 1928 found a region of puncture in which the potential gradient is independent of temperature and thickness—the so-called disruptive region. In 1929 Moon and Norcross concluded from their experimental data on glass, that there were three regions of breakdown.

Since the publication of the paper by P. H. Moon and A. S. Norcross[2] describing their experimental work on the breakdown of glass with direct potentials, there has been some question as to whether the same type of results would be obtained with alternating potentials. Our purpose was to determine if three regions of breakdown also existed for the a-c. case. We also hoped to find some relation between the alternating and direct breakdown voltages. Previous work by Hayden and Eddy[3] on the a-c. to d-c. ratio showed widely varying results, due perhaps to lack of knowledge of the types of breakdown and further complicated by edge effect. It was thought that careful tests made with edge effect eliminated, coupled with the present knowledge of different breakdown regions, might lead to a definite a-c. to d-c. ratio in each region.

For these tests it was decided to use glass because of its many advantages.

1. Previous tests have been made on glass, thus allowing a comparison of results.
2. Its characteristics are such that the tubing can be readily blown into spheres, thus eliminating edge effect.
3. Its homogeneous nature makes it desirable for breakdown investigations.

The disadvantages are:

1. Its physical structure is unknown.
2. Its chemical constitution is not exactly known for each batch of glass.

This paper describes the experimental results obtained at the Massachusetts Institute of Technology on the breakdown of glass with alternating potentials, and shows how these results compare with the d-c. tests of Moon and Norcross.

APPARATUS AND METHOD OF TEST

Alternating voltage (60 cycles) was obtained by means of a sine-wave motor-generator set and a 115/230-100,000-volt transformer. A motor-driven rheostat was used to vary the field voltage of the sine-wave set in order to obtain a uniform and easily-controlled rate of voltage rise. The transformer secondary voltage was read by means of a potential transformer and a Weston a-c. voltmeter.

Glass tubes 10 to 15 mm. in diameter and 300 mm. in length were sealed at one end and blown into spheres between 20 and 40 mm. in diameter. This procedure was similar to that used by Moon and Norcross and eliminated edge effect very nicely. These samples were placed in a mercury bath and filled on the inside with mercury. Contact was made to the internal electrode by means of a flexible wire suspended inside the tubing and to the external one by means of a steel container. (Fig. 1.) This was carefully lagged on the sides and top with asbestos and proved to be very effective in keeping the temperature uniform and constant. The voltage was impressed across the sample and increased by means of the motor-driven rheostat until puncture occurred. The sample was then carefully removed from the bath, all pieces being collected, cleaned, and measured. As it was not always possible to measure the thickness of the sample at the exact point of puncture, 5 to 10 micrometer readings were taken on the glass fragments near the puncture and the minimum value used as the approximate thickness at the point of breakdown.

The wave form of the generator was found to be practically sinusoidal; and since the transformer was operated at low saturation and with no series resistance in the primary circuit, it was assumed that the wave form of the voltage across the sample was also sinusoidal. The voltages read from the voltmeter were, of course,

r.m.s. values; but a better comparison with d-c. tests was obtained by using peak instead of r.m.s. values. Thus all readings were multiplied by $\sqrt{2}$, and all results given in this paper are peak kilovolts and not r.m.s. kilovolts.

EXPERIMENTAL RESULTS ON G-1* GLASS

The experimental results are shown in Fig. 2, where each point represents one breakdown test. To show clearly the different regions of breakdown, the logarithm of breakdown voltage (peak kv.) is plotted against the logarithm of thickness in microns. ($1\ \mu = 0.001$ mm.) There is a certain amount of scattering of the points, as can be expected in the results of any breakdown tests. However, it will be noted that this variation is not at all bad, and thus the curves can be located fairly exactly.

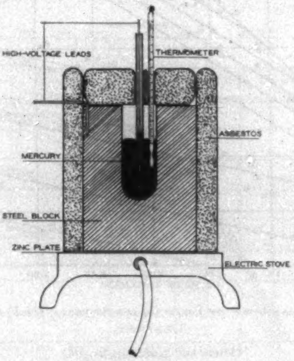

FIG. 1—SCHEME OF TEST APPARATUS

Fig. 2 shows clearly that with alternating potentials *there are three distinct regions of breakdown.* The tests at low temperatures and small thicknesses give a single curve of slope = 1. This represents the *disruptive region.* For somewhat higher temperatures, the curves depart from this straight line; and we have a set of parallel lines of slope = 2/3 breaking off from the disruptive-region line. The clusters of points for the 50 deg. and for 150 deg. curves, for instance, prove that these two are parallel or nearly so and that the slope is distinctly different from that of the 0 deg. curve. This is the *intermediate region.* At still higher temperatures we obtain another set of parallel lines having the slope of ¼. This is the *thermal region.* A comparison of the points at 150 deg. and 250 deg. shows very clearly that these two regions are distinct. The breaks in the 150 and 250 deg. curves may appear purely arbitrary, but they were found necessary in order to make a consistent family of curves when plotted against $(1/T)$. Thus the only questionable aspect of the curves as drawn is whether the transitions should be represented by sharp breaks or be slightly rounded. The accuracy of breakdown data does not warrant any statement as to which is correct. The present scheme, however, is the simpler and will be used in this paper.

In order to show more clearly the relations existing between breakdown voltage and temperature, curves of the logarithm of breakdown voltage (peak kv.) are plotted against the reciprocal of absolute temperature. (Fig. 4.) Here again three distinct slopes are noticed; zero slope for the disruptive region, slope = 430 for the intermediate and slope = 1,940 for the thermal.

How do the results of these a-c. tests compare with d-c. tests? To obtain a comparison, d-c. tests were also made on the same batch of lead glass. The results at room temperature (25 deg. cent.) are shown in Fig. 2 by the solid ▲'s. A very good check will be noted in both disruptive and intermediate regions. Thus we may say that on alternating current and in the disruptive and intermediate regions, *breakdown occurs at a peak voltage approximately equal to the d-c. breakdown voltage*

FURTHER DISCUSSION OF THE CURVES

The three regions of breakdown obtained by Moon and Norcross with G-1 glass and direct potentials are also found when alternating potentials are used. To facilitate comparison of our results with the previous ones, we have added Figs. 3 and 5 giving breakdown voltage for G-1 glass on direct potentials.[4] The a-c. curves (Figs. 2 and 4) are similar in every respect to the d-c. curves (Figs. 3 and 5).

For low temperatures and small thickness a linear relation (slope = 1) exists between breakdown voltage and thickness. The alternating breakdown gradient in this region is constant and has a magnitude of 3,550 kv. per cm., which is the same value obtained with direct current in this research.[5] The potential gradient is not affected by thickness or temperature.

With higher temperatures, an increase in temperature causes a decrease in the breakdown voltage for a given thickness. At intermediate temperatures (between the two previously mentioned regions) the voltage varies with the temperature according to some other relation, giving a third region which varies with the thickness as the 2/3 power.

The general form of the equation found to fit the curves is

$$V_b = K_d{}^n\ (10)^{\frac{b}{T}},$$

---

*A lead glass made by the Corning Glass Works.

[4] *Three Regions of Dielectric Breakdown*, Moon and Norcross, TRANS. A.I.E.E., V. 49, 1930, p. 755.

[5] This magnitude differs from the value of 3,100 kv. per cm. obtained by Moon and Norcross (Fig. 3 and Fig. 5) by about 14 per cent. The discrepancy may be due to a slight difference in the chemical or physical properties of the glass used in the two sets of experiments, though both tests were carried out with G-1 glass.

where K is a constant dependent on the region, n is the slope of the *log kv.* vs. *log d* curves and b is the slope of the *log kv.* vs. $1/T$ curves. Table I gives the a-c. peak values for K, n, and b while Table II gives the d-c. values as found by Moon and Norcross.

TABLE I—(A-C. PEAK VALUES)

Region	K	n	b
Disruptive	3,550	1	0
Intermediate	25.5	2/3	430
Thermal	1.635×10^{-3}	1/4	1,943

TABLE II—(D-C. VALUES)

Region	K	n	b
Disruptive	3,100	1	0
Intermediate	21.3	2/3	470
Thermal	0.618×10^{-3}	1/4	1,540

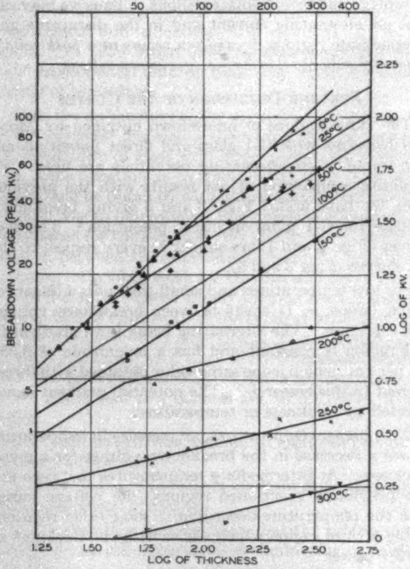

FIG. 2—BREAKDOWN OF LEAD GLASS SPHERES (G-1) ON 60 CYCLE ALTERNATING CURRENT

▲ = d-c. test points at 25 deg. cent.

By comparing Fig. 2 with Fig. 3 it can be seen that in the thermal and intermediate regions the direct breakdown voltage is higher than the a-c. peak value. Comparison of Fig. 4 and Fig. 5 shows that the intermediate region for alternating current is longer than that for direct current. This is shown to better advantage in Fig. 6, where the a-c. and d-c. curves are plotted on the same sheet. For simplicity only the 20μ and 100μ curves are given. It is probable that some of the differences are due to unavoidable experimental variations and that still others are caused by slight differences in the glass used in the two investigations. In the intermediate region, however, the average difference between the a-c. and d-c. curves is only about 6 per cent, which is undoubtedly within the experimental error.

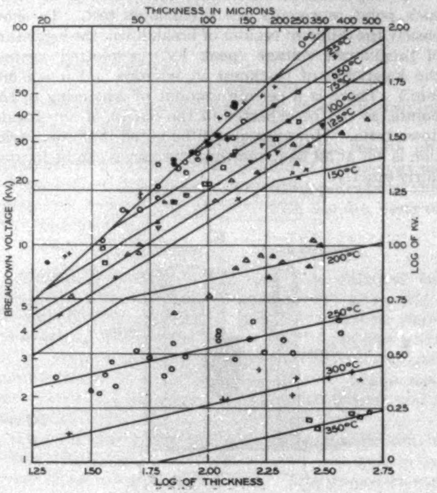

FIG. 3—BREAKDOWN OF LEAD GLASS SPHERES (G-1) ON DIRECT CURRENT

(Moon and Norcross, *loc. cit.*)

At the higher temperatures in the thermal region, the d-c. breakdown voltage appears to be distinctly higher than the peak alternating voltage. If r.m.s. values had been used instead of peak values, this difference would of course be even more marked. In the thermal region there appears to be no simple relation between a-c. and d-c. breakdown voltages or between the slopes of the curves. Such a relation could hardly be expected if we consider that in the a-c. case the heating is due to the total loss whose nature is not understood, and that the results are undoubtedly complicated by the effects of electrolytic polarization which is present in the d-c. case but partially eliminated in the a-c. case.

DISCUSSION OF THE POSSIBLE CAUSES OF BREAKDOWN

Disruptive Region. In the disruptive region the rate of application of voltage has no effect on the breakdown.

Samples were punctured with rates of application varying between 4 kv. per min. and 40 kv. per min. and no change in potential gradient was noticed. Breakdown in this region may be due to submicroscopic cracks in the surface of the glass. This theory was first expounded by Horowitz[6] and seems more logical than the molecular disruption theory, which gives a breakdown value much higher than the experimental values. The equation for breakdown according to the submicroscopic theory is

$$V_b = 1{,}200 \sqrt{\frac{\delta}{\mathcal{K}\,\lambda}} \text{ (volts per cm.)}$$

where

$\mathcal{K}$ = the dielectric constant
δ = the surface tension in dynes per cm.
λ = the depth of the crack in cm.

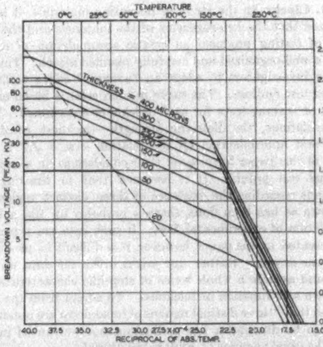

FIG. 4—BREAKDOWN OF LEAD GLASS SPHERES (G-1) ON 60 CYCLE ALTERNATING CURRENT

It will be noted that time should have no effect, according to this equation. Also, as the type of impressed voltage can have no effect on the depth of the crack, the dielectric constant, or the surface tension, the magnitude of V_b will be the same for alternating current and direct current. This was found to be true in our tests.

Intermediate Region. Unlike the disruptive region the intermediate has no constant potential gradient. From the experimental results obtained,

$$V_b = 25.51\, d^{2/3}\, 10^{\frac{430}{T}}.$$

It can be seen from this equation that the breakdown voltage is dependent on the thickness of the sample and the ambient temperature. The time factor appears to enter into this region and a study is to be made of its effect on the magnitude of the breakdown voltage.

Just what governs breakdown in this region is a question for debate. However, the ionization-by-collision theory seems to be a logical explanation of the results. This theory has been accepted for gases and liquids and it may be true also for solids.

Thermal Region. The thermal region, like the intermediate, has no constant breakdown gradient. The equation of this region was found to be

$$V_b = 1.635 \times 10\, d^{1/4}\, 10^{\frac{1940}{T}}.$$

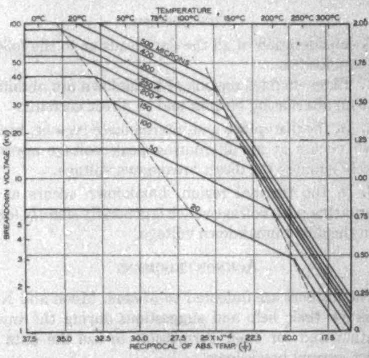

FIG. 5—BREAKDOWN OF LEAD GLASS SPHERES (G-1) ON DIRECT CURRENT

(Moon and Norcross, *loc. cit.*)

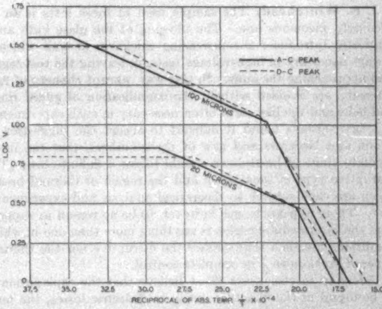

FIG. 6—COMPARISON OF D-C. AND A-C. RESULTS

Thermal breakdown is a function of thickness and temperature.

Heat is generated inside the sample by I^2R and other losses. It was noted during the tests that, by varying the rate of application of voltage, various values of breakdown voltage could be obtained. The rate which was found to be the most satisfactory was 300 volts per min., since further reduction in rate of voltage application had no effect on breakdown voltage.

---

[6] Das Griffithsche Prinzip und Dielektrische Durchschlegspestigkeit, *Archiv. für El.*, 18, 1927, p. 535.

When a direct potential is impressed across a sample of glass the sodium ions drift under the action of the outer field and gradually produce a poorly-conducting layer near the anode. With alternating potentials, the effect of electrolytic polarization is very small. This means that the a-c. conduction current will be greater than the direct current and therefore the I^2R losses will be greater with alternating current than with direct current. Hence the r.m.s. alternating breakdown voltage will be less than the direct breakdown voltage. This is substantiated by the tests described above.

CONCLUSIONS

A consideration of all the data leads us to the following conclusions:

1. Three distinct regions of breakdown are obtained, both on alternating current and on direct current.
2. In the disruptive and intermediate regions, breakdown occurs at an alternating peak voltage approximately equal to the direct breakdown voltage.
3. In the thermal region, breakdown occurs at an alternating peak voltage which is generally slightly lower than the direct breakdown voltage.

ACKNOWLEDGMENT

The authors are indebted to Messrs. Moon and Norcross for their help and suggestions during the investigation and for their permission to use the data on direct-current breakdown.

Discussion

J. B. Whitehead: The sample used in these tests is an exceedingly ingenious one. The blowing of the glass bulb automatically introduces the increasing thickness of wall which is always necessary in high-voltage tests, in leaving the test region and approaching the ends. In this way, abrupt changes of field intensity are avoided without the complication of guard rings, end-bells and the like, as is often necessary in such experiments.

I have always found it difficult to accept the suggestion of Moon and Norcross and now of these authors, that the intermediate stage of breakdown should follow a definite law. The disruptive type of breakdown and the region of thermal breakdown are each subject to theoretical analysis and experimental test. There appears to me, however, to be no reason to suppose that the intermediate region is anything more than one in which conditions are such that neither the disruptive nor the thermal types of breakdown is in complete control.

Referring to conclusion (3), I believe that the explanation is to be found in the fact that owing to dielectric losses, the temperature inside the specimen is higher than that which is measured on the thermometer.

W. A. Del Mar: The authors' main thesis is the contention that there exist, with alternating currents, as claimed by Professor Moon for direct currents, three distinct regions of dielectric failure, instead of two, as commonly believed. The evidence of this is that when breakdown is plotted against the reciprocal of the temperature, the graph appears as three lines of different slopes. The authors do not give this evidence, as all the experimental points are omitted from the graphs shown in Figs. 4.

They give experimental points in their graphs of breakdown voltage *versus* thickness, but they are of no significance in this place.

An actual attempt to transcribe the points from Fig. 3 to Fig. 4 resulted in a very erratic looking graph which might have been either what the authors claim or a smooth curve.

The authors, in justice to their thesis, should give Fig. 4 with the experimental points plotted.

W. A. Hillebrand: Doubt has been raised about the existence of an intermediate region of breakdown as postulated by the authors.

This at once brings up the question of the nature of glass, the material used in these tests. Glass is a physical solution, an electrolyte, whose constituents are ionized. It has the high negative temperature coefficient of resistance characteristic of electrolytes. Furthermore, some of its physical properties are indefinite. For example, it will flow at continuously applied stresses much below its short time mechanical ultimate. It therefore seems to me not impossible that in such a material there should be a region of dielectric breakdown intermediate between the disruptive and thermal, partaking of the nature of both and representing a transition stage.

For the same reasons, glass would seem to be a very unsatisfactory material to use in fundamental studies of dielectric breakdown because it is too complex and indefinite in its structure.

F. M. Clark: In the study of insulating materials, it is well recognized that the heterogeneity of the materials and the difficulties of testing produces an erratic accumulation of results despite a well-organized and carefully planned attack. This has led most investigators to adopt an "average" curve to fit the scattered test findings. The curve in such cases is based on the average of several tests for each thickness determined. With most insulations, the dielectric strength—thickness relation—can be best approximated by the relation kva. = AT^n. The authors of this paper have based their conclusions on a series of individual test points. It is assumed that in drawing the conclusions regarding the existence of three distinct regions of breakdown as has been done, there is probably on file a large accumulation of experimental data. If such data are typical of that presented in the paper, however, it is difficult to accept the conclusions drawn. Rather, one might break the data up still further and assume a whole series of step-like characteristics of breakdown as a function of thickness. To accept from the data presented that "three distinct regions of breakdown are obtained" appears to be drawing a fine distinction not warranted in the light of the usual vagaries of insulating material.

In experimental work involving a material such as glass, it must always be borne in mind that one is dealing with a material which may vary from batch to batch and which in itself bears little, if any, relation to other materials. Being a super-cool liquid, largely electrolytic in its electrical conductivity, conclusions drawn cannot safely be extended to apply to pure crystals or ceramic materials on the one hand, or to the usual organic commercial insulation on the other. The conclusions drawn by the authors, even if accepted, should be carefully limited to glass of the type under discussion which in itself might be more clearly described than has been done in the paper.

N. D. Kenney: The question of there being an intermediate region as raised by Dr. J. B. Whitehead and Mr. W. A. Del Mar, can best be answered by an examination of Fig. 2 and Fig. 4. Unless puncture tests on dielectrics are made with edge effect eliminated the field is decidedly non-uniform and the data are such as to make it impossible correctly to interpret the effect of thickness and temperature. The use of glass spheres removes the error introduced by concentration of stresses along an edge and a decided increase in the potential gradient is obtained. An examination of either Fig. 2 or Fig. 3 will show that it would be impossible to draw a line through the intermediate points that would be parallel to either the disruptive or thermal line. In the thermal region, as Dr. J. B. Whitehead has brought out, for thick samples and high temperatures the internal temperature becomes greater than the ambient temperature at the instant of breakdown. In 1931 Professor P. H. Moon presented a very interesting paper on thermal breakdown.*

Mr. Del Mar questioned Fig. 4 because there are no points shown. The data for Fig. 4 were obtained by taking any given thickness such as 200 μ and reading the breakdown voltages for various temperatures from Fig. 2. These values were plotted in Fig. 4 so as to show more clearly the relations existing between breakdown voltage and temperatures for a given thicknes of glass. The points would lie along the curves because of the manner in which they were obtained and there was no need to show them.

It is to be understood that no claim is made that this intermediate region is characteristic of all dielectrics. The physical construction of a dielectric is an important factor of its breakdown strength. This region seems to be characteristic of glass, quartz, and celluloid as consistent tests have shown and its physical form no doubt is closely related to its cause.

The Theory of Thermal Breakdown of Solid Dielectrics, by P. H. Moon, A.I.E.E. TRANS., Sept. 1931, p. 1008.

Magnet Steels and Permanent Magnets

Relationships Among Their Magnetic Properties

BY K. L. SCOTT*
Member, A.I.E.E.

INTRODUCTION

A GENERAL study of the magnetic properties of magnet steels and permanent magnets embraces a number of related problems. Of chief interest to the designer of magnets is the problem of determining the relationship between the open-circuit remanence of a permanent magnet and the various factors which determine its value. These factors include the magnetic characteristics or properties of the steel, as displayed by its hysteresis loop, and the shape and dimensions of the magnet. Of interest to the manufacturer of magnet steel are the questions of how chemical composition, melting practise, and rolling practise affect the magnetic and mechanical properties of the steel. The manufacturer of magnets is interested in the effect of the necessary manufacturing operations, such as heating for hot forming and annealing to increase machinability, upon the flux obtainable in the finished magnet; on the tendency of the steel to warp and crack upon quenching; and on the proper hardening treatment to use.

These interests overlap, of course, and include many special subjects, among which may be listed the manner in which various influences may affect the state of magnetization of a magnet, the correlation of the microstructure and mechanical properties of a magnet steel with its magnetic properties, the determination of a suitable criterion of magnetic quality, the development of accurate and convenient testing equipment, and various other matters of greater or less importance.

It is the purpose of this paper to present data relating to some of the above topics, which have been collected by the writer during the course of several years connection with the manufacture of permanent magnets, both in the laboratory and in the shop.

SYMBOLS AND NOTATIONS

The following symbols and notations will be used. See Fig. 1. All values of B are intrinsic or ferric induction.

B_{max} = The value of magnetic induction corresponding to the tip of a given hysteresis loop, in gauss.

H_{max} = The value of H corresponding to B_{max}, in oersteds.

B_s = The saturation value of flux density corresponding to an infinite magnetizing force.

B_r = Residual induction, the magnetic induction in a ring or infinitely long straight bar after the value of H has been reduced from H_{max} to O. The value of B at the intersection of the hysteresis loop with the B axis, in gauss.

H_c = Coercive force, the value of H required to reduce B from B_r to O in a ring or infinitely long bar. The value of H at the intersection of the hysteresis loop with the H axis, in oersteds.

B_{rem} = Remanence, the magnetic induction at the magnetic equator of a permanent magnet with no external magnetizing or demagnetizing force. Values of B_{rem} given in this paper are without pole pieces on the magnets, in gauss.

L = The actual developed length of a magnet.

A = The area of cross section of a magnet.

D = The equivalent diameter of a magnet $= 2\sqrt{A}/\sqrt{\pi}$.

L/D = The dimension ratio of a permanent magnet.

$(BH)_{max}$ = The maximum value of the product of the coordinates of the demagnetization curve for a given steel. The demagnetization curve is the portion of the hysteresis loop between B_r and H_c.

T = Hardening temperature, absolute scale.

T_0 = Optimum hardening temperature, absolute scale.

FACTORS THAT DETERMINE THE REMANENCE OF A PERMANENT MAGNET

Of the subjects enumerated in the introduction, the first is the one that has been of greatest technical interest to the writer. During the course of several laboratory investigations connected with shop problems, advantage was taken of the opportunity to secure data which might be used for the purpose of making generalizations regarding relations among magnetic properties of magnet steels and permanent magnets.

The specific problem was to find out exactly the way in which the remanence of a magnet is related to its shape and dimensions as well as to the magnetic properties of the material of which it is made. Although it requires the complete family of hysteresis loops for a given piece of magnet steel to portray all of its various magnetic characteristics, it was felt that possibly the

---

*Western Electric Company, Inc., Hawthorne Station, Chicago, Ill.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

combined influence upon the remanence of a magnet of the sum of these characteristics could be expressed in terms of the values of B_r and H_c for the material. Such an assumption, if valid, would simplify the problem considerably.

It is true that in the literature on the subject there are several papers[1,5,6] describing more or less accurate methods by means of which a designer may predict the flux of a given magnet provided the demagnetization curve for the steel is known. But these methods are laborious, and unless a complete redesign is worked out for each case, they do not answer such questions, for example, as how much a certain change in B_r or H_c will affect the remanence of a given magnet, other factors remaining constant.

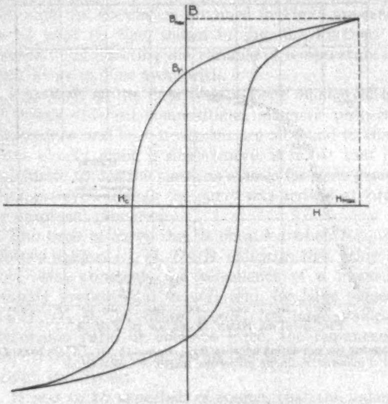

Fig. 1—Hysteresis Loop of Magnet Steel

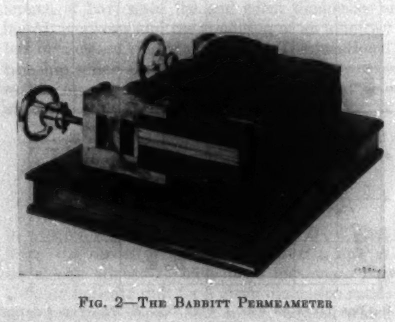

Fig. 2—The Babbitt Permeameter

Used for making magnetic measurements on any kind of magnet steel

Because the flux value of a magnet is affected by shape as well as other factors, and because magnets are made in a bewildering variety of shapes, it was decided to confine the investigations to straight bar magnets and leave the matter of the effect of shape on flux for a later study.

Test Specimens. Accordingly, a large number of straight bars of magnet steel was used for test specimens. Each of the bars was 12 in. in length. In the lot were bars of 1/8 by 1-1/2 in., 1/4 by 1/4 in., 3/16 by 3/4 in., 1/4 by 1-1/4 in., 3/4 by 5/8 in., and 3/8 by 1/2 in. cross sections. All of the types of steel available were used, including 0.9 to 3.5 per cent chromium steel, 0.85 per cent manganese steel, 5 per cent tungsten steel, and 20, 25 and 36 per cent cobalt steels. Along with this range in composition a range in coercive force of from 40 oersteds to 260 oersteds was available, accompanied by a variation in residual induction of from 6,000 gauss to 11,000 gauss.

Experimental Procedure. The test bars were hardened in the manner appropriate to each type of steel, except that some bars were purposely quenched from a high temperature in order to secure low values of B_r. After hardening, the demagnetization curve for each bar was determined by means of permeameter measurements, using the Babbitt[7] permeameter and a Grassot fluxmeter with lamp and scale. The control circuit of this permeameter is the conventional circuit for a ring test, as shown in Fig. 3. The magnetic data are all comparable since accurate measurements may be made with this permeameter on all of the above mentioned types of magnet steel.

Fig. 3—Control Circuit of the Babbitt Permeameter

Note that the connections are those of a simple ring test

Following the permeameter measurements, each bar was magnetized as a straight bar magnet in an air core solenoid. Field strengths of over 1,000 oersteds were applied to each bar. Upon removal from the solenoid the flux density at the middle of the bar was measured by means of a search coil and the Grassot fluxmeter with lamp and scale. It is the flux density measured in this way that is referred to in this discussion as the remanence of a magnet, or B_{rem}.

After the measurements at 12-in. lengths were com-

---

1. For references see end of paper.

pleted, each bar was cut in succession to 10, 8, 6, 4, and 2-in. lengths by removing 1 in. of material from each end except that in the case of some of the bars of larger cross-section the lengths of 10, 6, and 2 in. were omitted.

Remanence measurements were made at each of the above lengths. The bars were remagnetized for each new measurement of B_{rem}.

The foregoing experiments made available for analysis a wide range of values of the associated variables B_{rem}, B_r, H_c, length L, and cross-sectional area A.

Analysis of Data. The values of remanence *versus* length for a number of the straight bar magnets are plotted in Fig. 4 to show the range of values existing in different bar magnets of the same length, when fully magnetized. The differences in B_{rem} for a particular length of bar are due to the differences in B_r, H_c, and crcss-section of the various samples.

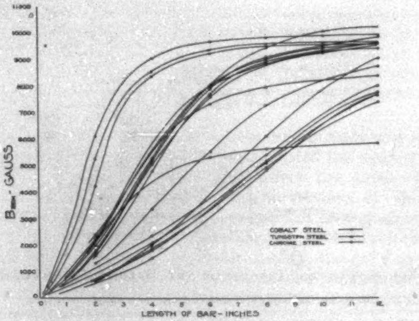

FIG. 4—CURVES OF REMANENCE *vs.* LENGTH FOR STRAIGHT BAR MAGNETS OF DIFFERENT CROSS-SECTIONS AND MATERIALS

The chief characteristic that the curves of Fig. 4 have in common is a resemblance in shape to a normal induction curve and an asymptotic approach to limiting values of B_{rem} as the lengths increase.

In Fig. 5 is shown the result of plotting B_{rem}/B_r *vs.* $(L/D)\sqrt{H_c}(T/T_0)^2$ for the same set of bars. This combination of variables was arrived at purely by a cut and try method, but as shown, a surprisingly good correlation is obtained.

It should be mentioned in connection with Fig. 4 that it was found that the data relating to some of the bars did not fit the curve satisfactorily if B_{rem}/B_r was plotted against $L\sqrt{H_c}/D$, but in each case where this was so the bar had been quenched from above or below the optimum hardening temperature. It was found, however, that the data from these bars could be correlated with those from the properly hardened bars if B_{rem}/B_r were plotted against $(L/D)\sqrt{H_c}(T/T_0)^2$ in which T is the actual, and T_0 is the optimum hardening temperature on the absolute scale. The ratio T/T_0 is, of course, equal to unity for bars properly hardened. The definition of the optimum hardening temperature will be given later.

After this empirical correlation was obtained, it was suggested that B_{rem}/B_r *vs.* $L\sqrt{H_c}/D\sqrt{B_r}$ would be preferable as a choice of variables, from theoretical considerations based upon the assumption of uniform magnetization in the magnets. Although it can be shown that this assumption is not fulfilled in the actual case of straight bar magnets, this method of plotting gives as good a correlation as is shown in Fig. 5. Such a result might be expected, since the values of B_r commonly encountered range from 9,000 gauss to 11,000 gauss, thus differing from 10,000 gauss by 10 per cent at most. The square root of B_r, therefore, differs from 100 by not more than 5 per cent in most cases, whence

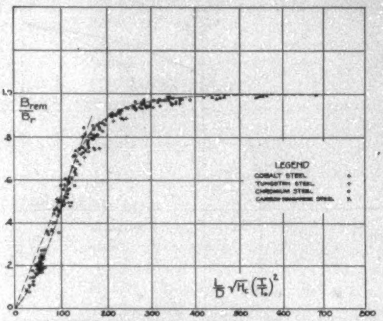

FIG. 5—THE SAME DATA AS IN FIG. 4

Showing the correlation between B_{rem}/B_r and $(L/D)\sqrt{H_c}$ for bars of any kind of material, magnetic properties, length or cross-section

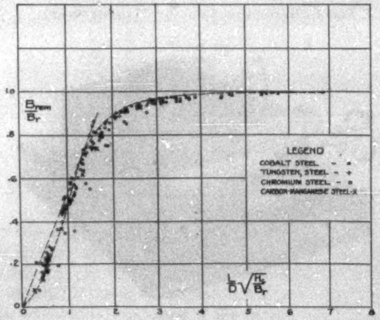

FIG. 6—THE DATA OF FIG. 4 WITH B_{rem}/B_r PLOTTED AGAINST $L\sqrt{H_c}/D\sqrt{B_r}$

it follows that dividing $L\sqrt{H_c}/D$ by $\sqrt{B_r}$ shifts the relative position of the abscissas of the points in Fig. 5 by not more than 5 per cent in most cases. Fig. 6 illustrates the results obtained by the second method of plotting.

Dimensional considerations favor the use of the quantity $L\sqrt{H_c}/D\sqrt{B_r}$, however, since this quantity, like B_{rem}/B_r, is dimensionless, whereas $L\sqrt{H_c}/D$ is not. For this reason it is felt that the method of plotting shown in Fig. 6 is to be preferred to that of Fig. 5 although the correlation obtained in Fig. 5 appears to be as good as that shown in Fig. 6. Further, the necessity for injecting the variable of temperature into the picture is done away with.

Inasmuch as the data from a large number of bars of widely different compositions, magnetic properties, dimensions and heat treatment are all found to cluster quite closely along a single curve, it is felt that it is legitimate to use the curve as a basis for some generalizations, even though the curve was arrived at largely by empirical processes.

The type of curve that is obtained when B_{rem}/B_r is plotted against $L\sqrt{H_c}/D\sqrt{B_r}$ indicates that other factors being constant, the remanence of a magnet is roughly proportional to $\sqrt{B_r}$ and, for large values of $L\sqrt{H_c}/D\sqrt{B_r}$, in other words, for large values of dimension ratio or coercive force, the remanence is practically equal to B_r. This fact is of interest from a design standpoint.

It was to be expected, of course, that the values of B_{rem} would approach B_r as a limit for high values of length of bar, since the end effect diminishes as the length increases and the condition of an infinitely long bar or a closed ring is simulated. The functional relationship which the quantity $L\sqrt{H_c}/D\sqrt{B_r}$ bears to the ration B_{rem}/B_r is not known. A fairly good fit of the observed data is given by the expressions:

$$r = \frac{q^{1.5}}{2.15} \qquad q = O \text{ to } q = 1.25 \text{ and}$$

$$r = e^{-\frac{0.8}{q^{2.75}}} \qquad q = 1.25 \text{ to } q = \infty$$

in which $r = B_{rem}/B_r$ and $q = L\sqrt{H_c}/D\sqrt{B_r}$, but aside from the direct proportionality of B_{rem} and B_r, the equations appear to have little meaning. However, they do indicate that for a given dimension ratio, there is a practical upper limit to H_c, beyond which very large increases in H_c are necessary to produce small increases in the ratio of B_{rem} to B_r. Considerable interest attaches to the fact that the dimension ratio L/D and $\sqrt{H_c}/\sqrt{B_r}$ are of equal weight in affecting the remanence of a magnet. It is also worth noting that the value of B_{rem} is independent of the contour of the cross-sectional area. It is possible that this would not hold for dimension ratios less than one, but it does appear to hold for dimension ratios of practical importance. As shown in Fig. 5, a line drawn through the origin and tangent to the dotted curve of that figure has its point of tangency at values of B_{rem}/B_r and $L\sqrt{H_c}/D\sqrt{B_r}$ of approximately 0.65 and 1.25 respectively. It will be shown later that this is the point of maximum efficiency, *i.e.*, the point at which are obtained the highest values of B_{rem} or external magnetic energy per unit volume of steel.

It follows, if this is true, that magnets should be designed so that $L\sqrt{H_c}/D\sqrt{B_r} = 1.25$, and with this as a basis, the nomogram of Fig. 7 was laid out. The use of this chart to design a magnet for maximum efficiency, is illustrated by the dotted lines of the figure. In the case shown a total flux in the magnet of 3,000 maxwells is desired, and a steel with a B_r of 10,000 gauss and a coercive force of 54 oersteds is assumed. The correct values of A and L are found to be 0.461 cm.² and 13 cm., respectively, and the dimension ratio is 17.

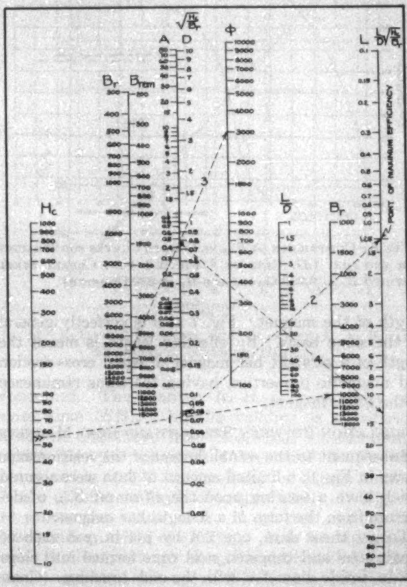

Fig. 7—Nomogram Chart for Permanent Magnet Design for Maximum Efficiency. Based on the Curves of Figs. 6 and 10

It should be borne in mind throughout this discussion that Figs. 4, 5, 6 and 7 apply directly only to straight bar magnets. Formed magnets with short air-gaps with or without pole pieces, will have higher remanence values than are shown by the curve of Fig. 6. This is because, compared with straight magnets, their effective lengths are greater than their actual lengths. The difference between effective and actual lengths is negligible, however, except for magnets whose poles are brought quite close together, either actually or by means of pole pieces of soft iron. Watt-hour meter damping magnets are good examples of magnets whose poles are brought thus closely together without the aid of pole pieces.

On the other hand, the general conclusions drawn from the curve of Fig. 6 are applicable to magnets of any shape if L is assumed to stand for the effective length of the magnet. Fig. 7 also is perfectly general on the same basis. By effective length is meant the length of a straight bar magnet of equal cross-section and magnetic properties, having the same remanence as the given magnet.

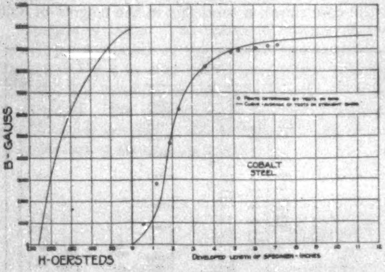

FIG. 8—COMPARISON OF B_{rem} *vs.* LENGTH CURVES FOR STRAIGHT BAR AND 2-IN. I.D. RING OF 1/4-IN. x 1/4-IN. COBALT STEEL IN WHICH $B_r = 9{,}980$ GAUSS AND $H_c = 230$ OERSTEDS

CORRELATION BETWEEN STRAIGHT AND BENT MAGNETS

Subsequent to the establishment of the relationships shown in Fig. 6, a limited amount of data were secured which have a bearing upon the effect on B_{rem} of departure from the form of a straight bar magnet.

To get these data, one 1/4 by 1/4 in. rod each of cobalt steel and tungsten steel were formed into rings of 2-in. inside diameter, with the ends touching. Companion test bars were cut adjacent to each end of the rods used in forming the rings. All three pieces of each kind of steel received as nearly identical heat treatments as possible, even to heating and cooling the straight test bars at the time of forming the rings. After hardening, demagnetization curves were obtained on each of the two test bars of tungsten steel and of cobalt steel. Then data for B_{rem} *vs.* length curves were obtained from both the test bars and rings by the process of cutting off the ends and remeasuring B_{rem} already described.

The demagnetization curves and the B_{rem} *vs.* length curves, for the two straight cobalt steel bars are practically identical. Inasmuch as these bars were cut adjacent to the ends of the bar from which the ring was formed, and heat treated with it, it is safe to assume that the material in all three samples is alike magnetically, and that the demagnetization curve for the ring is the same as for the straight bars. The same conclusions hold for the tungsten steel, as shown in Fig. 9.

It follows then that it is valid to compare the B_{rem} *vs.* length curves for the straight bars with those for the rings, and conclude that all differences in the curves are due to differences in shape. It is interesting to note that the ring for cobalt steel yields the same curve for B_{rem} *vs.* length as the straight bar, but that, in the case of the tungsten steel, the proximity of the ends of the ring has an appreciable effect on the value of B_{rem}, causing the curve for B_{rem} *vs.* length to turn upwards for those lengths corresponding to short air gaps.

Additional data along these lines would be very useful, and should include measurements on magnets with pole structures having well defined air gaps.

CRITERIA OF MAGNETIC QUALITY OF PERMANENT MAGNET STEELS

A number of quantities determinable by magnetic measurement has been proposed at various times by different investigators for use as criteria of magnetic quality of magnet steels. Among these quantities may be listed $(BH)_{max}$⁽¹⁾, the maximum product of the coordinates of the demagnetization curve; and the quantities $B_r\, H_c$⁽²⁾, B_r/B_{max}, $B_r\, H_c/B_{max}$ and B_r/H_c⁽³⁾. High values of all of the proposed criteria except the last were considered desirable.

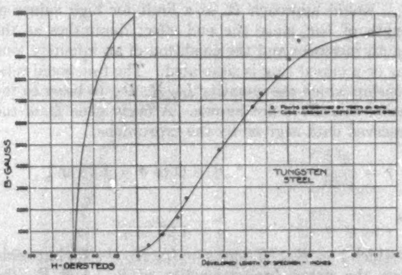

FIG. 9—COMPARISON OF B_{rem} *vs.* LENGTH CURVES FOR STRAIGHT BAR AND 2-IN. I.D. RING OF 1/4-IN. x 1/4-IN. TUNGSTEN STEEL IN WHICH $B_r = 10{,}830$ GAUSS AND $H_c = 59$ OERSTEDS

The form B_r/H_c has decided disadvantages, since a low value of the criterion is obtained when B_r is small as well as when H_c is large, and low values of B_r are distinctly undesirable in view of the fact that B_{rem} is directly proportional to B_r. The ratio B_r/B_{max} was found to be practically constant for some types of steel, regardless of the value of H_c, and thus was of no value as a criterion. The quantity $B_r\, H_c/B_{max}$ would accordingly amount to a constant times H_c and would give no actual weight to the value of B_r. These three criteria would, therefore, fail either to indicate a choice between different types of magnet steel or to aid in the selection of an optimum heat treatment for a given kind of steel.

This leaves the quantities $(BH)_{max}$ and $B_r H_c$ as the only ones not obviously faulty. The first was proposed by S. Evershed in a noteworthy paper in the *Journal* of the Institution of Electrical Engineers for September 1920, in which he showed that the quantity $(BH)_{max}$ is a measure of the maximum amount of external magnetic energy which can be supported per unit volume of a given magnet steel, and that this in turn defines the term "magnetic quality" as applied to magnet steel.

Evershed's derivation of his criterion of magnetic quality, given in the article noted above, is complete and convincing, but it was thought desirable to obtain experimental verification. The data from the bars of Fig. 4 were used to this end. In Fig. 10 is shown a number of curves each corresponding to a different type of magnet steel. The demagnetization curves for the bars are shown plotted in the usual way, and to the right of these are plotted the curves of (BH) *vs.* B. To the right of these are plotted further the experimentally determined curves of B_{rem} *vs.* length for the bars in question.

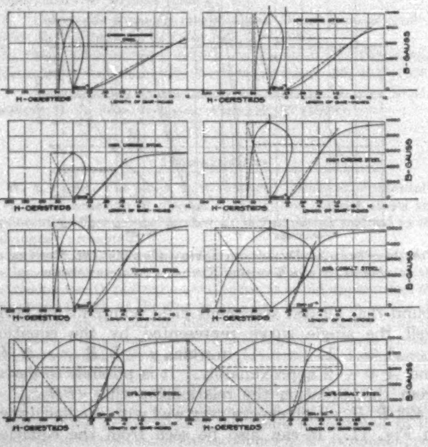

Fig. 10—Curves Showing Experimental Verification of Validity of Evershed's Criterion for Magnetic Quality of Permanent Magnet Steels

Fig. 10 shows that if tangents to the curves of B_{rem} *vs.* length are drawn through the origin the point of tangency in each case indicates the value of B_{rem} and length at which the ratio of B_{rem} per unit length or volume of steel is a maximum, and it is clearly demonstrated that in each case these values of B_{rem} coincide closely with the values of B for which the product (BH) is a maximum. The writer feels that this constitutes a sufficiently convincing verification of the correctness of Evershed's criterion.

The chief objection to the use of Evershed's criterion is that a number of points on the demagnetization curve for a piece of magnet steel must be known before the numerical value of the product $(BH)_{max}$ can be determined. The quantity $B_r H_c$ is more easily obtained than $(BH)_{max}$ but its validity as a criterion cannot be established from theoretical considerations. Accordingly, the values of $(BH)_{max}$ and $B_r H_c$ were determined by actual measurement for a large number of bars of different kinds of magnet steel. In Fig. 11 are shown the values of $B_r H_c$ plotted against the corresponding values of $(BH)_{max}$. It is felt that these points lie closely enough along the straight line in that figure to warrant the use of $B_r H_c$ as a criterion of magnetic quality of magnet steel for all practical purposes. In cases where very accurate comparisons are required, it may be necessary to go to the greater trouble of determining $(BH)_{max}$.

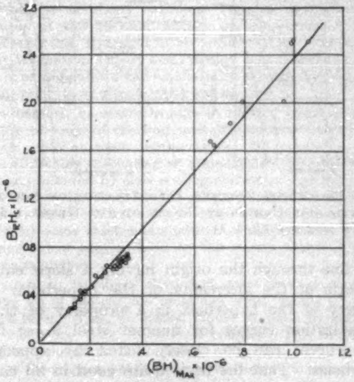

Fig. 11—Relation Between the Quantity $B_r \times H_c$ and Evershed's Criterion, $(BH)_{max}$

Referring to a previous mention of optimum hardening temperatures, it will be understandable now to state that the optimum hardening temperature for a given type of steel is that temperature at which a maximum value of $(BH)_{max}$ is obtained, or practically speaking, a maximum value of $B_r H_c$.

Fit of Demagnetization Curve by Hyperbola

It will be noted that the points on the demagnetization curves for which the product (BH) is a maximum are given quite accurately in each case by the intersection of the demagnetization curve with a line through the origin having the slope B_r/H_c. That this should be so follows from the fact that any demagnetization curve for magnet steel may be closely approximated by a rectangular hyperbola whose equation is $B = a - k/(H + b)$ in which a, b, and k are parameters of each particular curve. It is a mathematical property of the foregoing rectangular hyperbola that the coordinates whose product is a maximum are located by a line through the origin having a slope equal to the ratio of the intercepts of the hyperbola. This property of the hyperbola is a property of the demagnetization curves for magnet steel in so far as these curves can be closely fitted by appropriate hyperbolas. That the fit is quite good in all cases is shown by Fig. 12 in which hyperbolas calculated for each demagnetization curve are shown by dots and the observed points by a full line. The graphical method of Fig. 10 for determining the point on each demagnetization curve the product of whose coordinates is a maximum is more accurate than the method of plotting the curve of (BH) *vs.* B, because the latter curve is usually quite flat-topped and its maximum is hard to locate exactly. The fact that the curve is flat-topped explains why many methods of magnet design give good results. It is because about equal efficiencies are obtained in any case over a fairly wide range of values of $B_{rem.}$

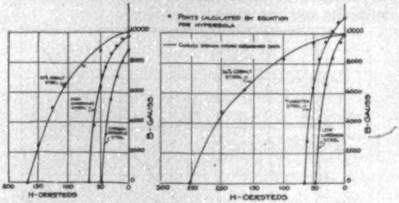

FIG. 12—CURVES SHOWING APPROXIMATION OF ACTUAL DEMAGNETIZATION CURVES BY POINTS ON THE GENERAL HYPERBOLA, $B = a - k/(H + b)$

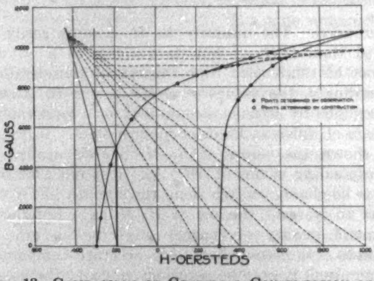

FIG. 13—COMPARISON OF GRAPHICAL CONSTRUCTION OF THE DESCENDING PORTION OF THE HYSTERESIS LOOP WITH ACTUAL MEASURED DATA

Note the lack of agreement for positive values of H

A further application of the idea that the demagnetization curve can be represented by a hyperbola is made by Mr. E. A. Watson.[4] Watson applies a graphical construction for a hyperbola to the demagnetization curve and extends the construction into the region of positive values of H, thus providing a means of extrapolating the hysteresis loop to the saturation value of B. It has been the writer's experience that Watson's graphical construction cannot be legitimately extended into the first quadrant because the curve thus predetermined almost always lies considerably under the true curve, and yields too low a value for the saturation flux density. Fig. 13 illustrates the case in point.

If, instead of potting B *vs.* H for the points of the demagnetization curve, we plot B/B_r *vs.* H/H_c, it is found that all test specimens yield points fitting fairly well the single curve represented by the equation $y = A\,(x + 1)/(x + A)$, in which $y = B/B_r$, $x = H/H_c$ and $A = \sqrt{2}$ approximately. It is possible to derive from this equation the relationship that $(BH)_{max} = 0.423\ B_r\,H_c$ which checks very well with the line drawn in Fig. 11. It can also be seen from the equation $y = A\,(x + 1)/(x + A)$ that the representation of the demagnetization curve by a hyperbola cannot be extrapolated to give the correct value for B_s since for values of H approaching infinity, the equation yields the result that $y = B_s/B_r = A = \sqrt{2}$ whence $B_s = \sqrt{2}\,B_r$, while values of B in excess of $\sqrt{2}\ B_r$ are commonly encountered at ordinary values of H.

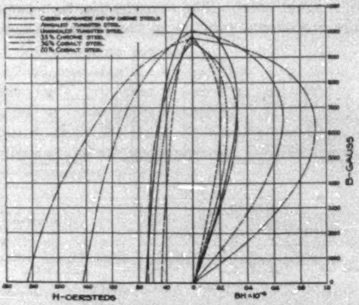

FIG. 14—TYPICAL DEMAGNETIZATION CURVES AND CURVES OF BH *vs.* B FOR VARIOUS KINDS OF MAGNET STEEL

CHARACTERISTIC CURVES FOR MAGNET STEEL

In Fig. 14 are shown demagnetization curves and (BH) curves for the various types of magnet steel with which the writer has had experience. It should be remembered that while these curves are more or less typical of the steels in question, there is no one curve which can be given as the curve for the material. There will be as many curves as there are samples tested, because magnetic characteristics of a piece of magnet steel, or any other magnetic material depend upon the whole previous thermal history of the sample from the time of melting to the time of testing, the amount of hot and cold working the sample has received, and the conditions of stress in the material at the time of testing. The relation of all of these variables to the remanence of a permanent magnet, fortunately, is focussed, as it were, in the values of B_r and H_c for the material, and the relation of these variables to B_{rem} is as shown by Fig. 6.

Discussion

W. A. Codd: The paper quite evidently checks experimentally Evershed's criterion of magnetic quality for magnet steels and apparently offers a considerably simplified design method in the nomogram presented.

In Fig. 9, from the data given on the closed ring sample, 2 in. inside diameter and ¼ in. by ¼ in. section, together with the maximum length plotted on the curve, it would appear that the developed length of the ring sample has been taken as the circumference on the outside diameter of the ring rather than the mean length which appears to be more logical. Is there a reason for this or is the 2 in. inside diameter of the ring merely an approximate figure.

Also in connection with Fig. 9, what is the reason for the difference of the effect of proximity of the ends of the magnet for Tungsten steel as indicated in this figure as compared to this effect for the Cobalt sample as shown in Fig. 8. It would appear that the reason for this lies in the facts brought out in the paper in regard to the relatively small effect of increases of H_c, or equivalent changes, as B_{rem}/B_r approaches unity. Is this correct?

There is one other question in regard to the data taken on the ring samples. How was the measurement of the B_{rem} flux value made on the ring sample for maximum length with the ends touching?

It is understood that the measurements of B_{rem} were made, after the sample was magnetized, by use of a search coil. In this case to measure the total flux of the magnet at this neutral section it would be necessary to draw the coil from the neutral section off the end of the magnet. Otherwise only the leakage flux would be measured, of course.

In regard to the nomogram shown in Fig. 7, for use in permanent magnet design, this apparently offers a decided simplification over Evershed's step-by-step method of calculation. However, for use in connection with bent magnets, as the author points out, it is necessary to use the effective length rather than the actual length of the magnet. Figs. 8 and 9 evidently offer a method of obtaining this effective length for a given shape of bent magnet. Is it necessary to make such an experimental determination for each particular shape which is to be used, or is there a general method for obtaining the effective length? If such a method of readily calculating this effective length were available, the design nomogram would be extremely valuable.

The author mentions variations between samples due to differences of the thermal history of the sample. In connection with this, Evershed in his article of Aug. 1925 on "Permanent Magnets in Theory and Practise" discusses these thermal effects in considerable detail emphasizing in particular two effects which he refers to as ultra-heating and spoiling.

Ultra-heating, he states, results in reduced values of B_r due to failure of some of the iron molecules to return to the α or magnetic state at room temperatures. He suggests a curing process consisting of heating to a moderate temperature (1,380 deg. fahr.) followed by slow cooling and states that this process should always be used by the magnet maker before forming magnets. This does not seem to agree with the process recommended by some steel manufacturers which indicates that the total amount of heating used by the magnet maker should be kept at a minimum.

In regard to "spoiling," Evershed states that this consists of breaking up of the carbide molecules which results in reduced coercive force. This, he states, should be cured by heating to about 2,370 deg. fahr. for several minutes. This he indicates should be done at the mills before rolling into bars. If this is not done the magnet maker will receive steel low in coercive force.

Evershed gives the above particularly in regard to Tungsten steel. Has the author any experience in regard to these points?

The author has made numerous measurements on a large number of samples of each of the various kinds of magnet steel available. Does he find that any of these steels show any better uniformity than others when exercising equal care in control of heat treatment?

K. L. Scott: The ring magnets, about which Mr. Codd has asked were formed hot about a mandrel roughly two inches in diameter. The developed length, as given in the paper, represents the actual mean length of the ring. Mr. Codd's interpretation of Figs. 8 and 9 is correct. A gap was ground between the ends of the ring magnets, large enough to admit a small search coil, before any flux measurements were undertaken, although an initial value of B_{rem} could have been obtained before this was done by following the procedure for a standard Rowland ring test.

A general method of determining the effective length of a magnet, with or without pole pieces, has not been worked out to the writer's knowledge. Such a general method would probably involve the calculation of internal and external reluctances for a given design of magnet and pole pieces, and the calculation of effective length from these reluctances either by reference to an empirical curve or formula.

The writer has had no first hand experience with steel mill practise in the manufacture of tungsten magnet steel. His own experience does bear out the recommendation that the total amount of heating by the magnet maker should be kept as low as possible. The writer's experience does not enable him to differentiate between the various kinds of magnet steel as regards uniformity of magnetic quality when exercising equal care in control of heat treatment. It appears to the writer that exact control of the heat treatment of magnetic materials is yet to be attained.

An Induction Motor with Paralleled Rotor and Stator

BY A. G. CONRAD[1]

and

R. G. WARNER[1]
Member, A.I.E.E.

***Synopsis.**—A wound rotor induction motor may be operated with the stator and the rotor independently magnetized, (neither supply frequency corresponding to the slip frequency). If the stator and rotor are paralleled the pull-out torque as a motor is approximately doubled and the continuous horsepower output may be increased, and as an induction generator, the maximum kva. output is increased. It may be operated simultaneously as a motor and as a generator.*

This method of operation was new to the authors and to several eminent induction motor designers and as no reference has been found to others employing this principle, the theory has been developed and is presented with the experimental results of tests.

INTRODUCTION

WITH machines wired as in Fig. 1 it is possible to transfer power from rotor to stator or from stator to rotor at high frequency and while this is taking place, the machine can either receive power or deliver power at its shaft. Using more general terms, if stator and rotor are independently excited then power can be delivered to the machine through three channels namely, the stator, the rotor or the shaft. When energy is supplied through two of these channels it can be taken from the third and when it is supplied to one it can be taken from one or both of the other two.

The rotor and stator voltage and frequency can be adjusted to the same values; thus it is possible to parallel stator and rotor and make the machine operate either as a double motor or double generator.

PRINCIPLE OF OPERATION

Fig. 1 shows a wiring diagram of a wound rotor induction motor with the rings of the motor connected to a synchronous machine. The armature of the synchronous machine serves to provide a path for the secondary current and consequently the induction motor can be started. The induction motor will behave much the same as it would with its rings short-circuited. If the phase rotation of the stator was in the order of 1-2-3 the voltages induced in the rotor would be a low-frequency voltage with a phase rotation of *a-b-c*. This will cause three currents to flow in the synchronous machine armature that are 120 deg. out of phase and in the order of *A-B-C*. This means, of course, that if the windings are placed on the machine as shown in the diagram that the induction motor will rotate in a clockwise direction.

With the stator disconnected from the supply and short-circuited directly or through transformers, and power supplied to its rotor from the alternator in Fig. 1, the induction machine may be started again. If the phase rotation of the alternator is *C-B-A* the induction machine will rotate in the same direction as above and the low-frequency currents in the stator will be in the direction 3-2-1.

If the stator is now supplied as usual and at the same time the rotor is supplied from the alternator with phase rotation *C-B-A* the supply transformers will act as a low impedance path for the slip-frequency currents in the stator and the alternator will complete the path for the slip-frequency currents of the rotor. The magnitude of the voltage impressed on the rotor is dependent on the field excitation of the synchronous machine. The frequency of the voltage depends upon the speed of the synchronous machine. By adjustment of the input of the d-c. machine the frequency in the rotor circuit can be made equal to the stator frequency. By the field adjustment of the synchronous machine the rotor voltage can be made equal to the stator voltage. When the rotor and stator have the same voltage and frequency they can be synchronized and electrically connected through the switch S_1 of Fig. 1. The circuit to the synchronous machine can now be opened at S_2. The induction motor will continue to operate with its rotor and stator electrically and magnetically connected; both the stator and rotor will receive power from the line. The machine will rotate at a speed less than synchronous speed. The high-frequency current in the stator will be in the order of 1-2-3 and the low-frequency currents in the order of 3-2-1. The high-frequency currents in the rotor will be in the order of *c-b-a* and the low frequencies in the order of *a-b-c*. The machine when

Abridgment of a thesis submitted by A. G. Conrad to the Graduate School of Yale University, June 1931.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

so connected has characteristics similar to those of the normal induction motor. When loaded the speed decreases slightly.

When driven above synchronous speed the machine acts as an induction generator. The low-frequency currents in the stator and rotor are opposite in phase rotation to what they are as a motor and are in the order of 1-2-3 in the stator and *c-b-a* in the rotor.

The characteristics of the motor with its rotor and stator paralleled can be determined by applying ordinary induction motor theory. Using slip as parameter it is possible to determine the torque, stator, copper loss and rotor loss, etc., by the power fed into the stator and for the same slip determine value for the same items which are produced by the power fed into the rotor.

Curve *A*—Speed torque curves of machine with rotor and stator paralleled
Curve *B*—Speed torque curves of machine with rotor short-circuited

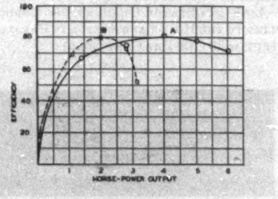

FIG. 3

Curve *A*—Efficiency of the motor with its rotor and stator paralleled
Curve *B*—Efficiency of the motor with its rotor short-circuited

EXPERIMENTAL INVESTIGATIONS

Calculations and analysis of operation were checked experimentally. The machine selected for tests was a Westinghouse wound rotor induction motor rated as follows:

Horsepower...... = 10 Stator volts....... = 220
Cycles........... = 60 Rotor volts....... = 206
Three-phase...... 1,140 r.p.m.
Serial No. 4191333

The motor has nearly a 1 to 1 ratio of stator to rotor turns.

In order to keep within the limitations of the laboratory circuits, the voltage on each phase was dropped to 110 volts, 60 cycles and the characteristics were determined with stator and rotor paralleled. The machine was operated both above and below synchronous speed to determine the characteristics as a motor and as a generator. In this machine the voltage supplied to each phase is a fundamental voltage while the current will contain not only a fundamental component but also a low-frequency component.

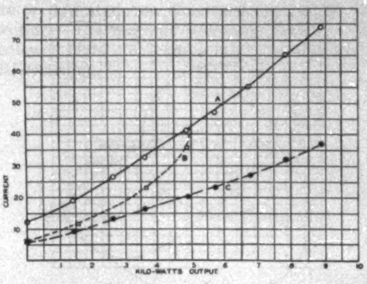

FIG. 4

Curve *A*—Line current delivered by generator with rotor and stator paralleled
Curve *B*—Current in stator phase of the generator with rotor short-circuited
Curve *C*—Current in stator phase of the generator with its rotor and stator paralleled

The results of these tests are shown as curve *A* in Figs. 2 to 5. For comparison curve *B* in each figure shows the characteristics of the motor with normal connections.

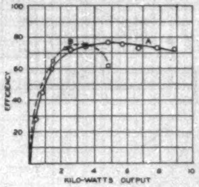

FIG. 5

Curve *A*—Generator efficiency with rotor and stator paralleled
Curve *B*—Generator efficiency with rotor short-circuited

Fig. 2 shows that the breakdown torque of the motor can be approximately doubled by using the stator and rotor in parallel; likewise that the generator capacity and maximum output can be increased by the parallel connection.

The relative efficiencies for the two methods of operation are shown in Figs. 3 and 5. With the parallel connection high efficiencies are obtained for large loads on account of reduced copper losses per unit output but the efficiencies are low for light loads because of larger iron losses and copper losses produced by the additional exciting current. The maximum efficiency for the two cases seemed to be approximately the same for both the condition of motor and generator action.

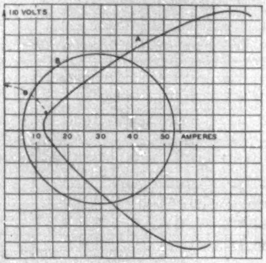

FIG. 6

Curve *A*—Locus of line current with rotor and stator paralleled
Curve *B*—Locus of line current with rotor short-circuited

The heating in the machine due to the copper losses will always be less for heavy loads when parallel connected than when the rotor is short-circuited. In Fig. 4 is shown the line current for different loads on the generator for each of the methods of operation. It can be seen that the phase current with the parallel connection will be less than the phase current when the generator is supplying the same load with its rotor short-circuited.

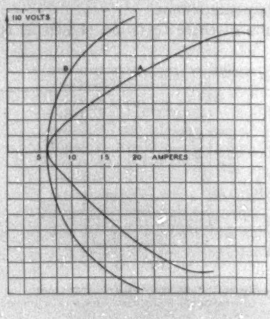

FIG. 7

Curve *A*—Locus of current in stator phase with rotor and stator paralleled
Curve *B*—Locus of current in same state phase with rotor short-circuited

In Fig. 6 is shown the circle diagram of the motor when the rings are short-circuited. The no-load losses for this machine are very small but it can be seen that when the rotor and stator are paralleled that the no-load line current contains a larger power component. This is because of the increased iron losses due to the high-frequency rotor flux and also the super-position of the two fluxes traveling in the iron at different speeds. In addition to this the exciting current in the rotor causes copper losses that increase the no-load input.

It will also be noted that the maximum power component of the input current is a little less than twice the maximum power component of the motor when its rings are short-circuited. This is caused by a slight terminal voltage drop with these heavy loads. It can be assumed that the heart-shaped diagram would have had a slightly higher maximum power component if the voltage had remained constant. The arithmetical sum of stator and rotor current was almost equal to the line current. If the rotor and stator constants were the same each current would be one-half the line current and when compared with the current with the rings short-circuited we would have current loci per stator phase as shown in Fig. 7.

FIG. 8—NO-LOAD CURRENTS OF MACHINE OPERATING WITH ROTOR AND STATOR IN PARALLEL. VOLTAGE APPLIED = 245

FIG. 9—LINE AND STATOR CURRENT FOR CONDITION OF 220 VOLTS APPLIED TO THE ROTOR AND STATOR IN PARALLEL. HORSEPOWER OUTPUT = 10 (100 PER CENT LOAD)

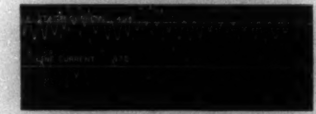

FIG. 10—STATOR AND LINE CURRENTS TAKEN BY MOTOR WITH ITS ROTOR AND STATOR PARALLELED SUPPLY VOLTS = 220; SPEED = 1040; HORSEPOWER OUTPUT = 20 (200 PER CENT LOAD)

The exciting current taken by the motor is indicated in the oscillogram of Fig. 8. It can be seen in Fig. 9 that some of the high-frequency waves have pointed peaks and the other maximum value of the same wave has a rounded point. This indicates a high saturation during part of the cycle.

When the machine is loaded, the high-frequency currents are slightly out of phase and the low-frequency currents are slightly out of phase. This is caused by different constants in the rotor from those in the stator, *i. e.*, the ratio of stator inductance to stator resistance is different than the ratio of rotor inductance to rotor resistance. It can also be seen that the low-frequency current is slightly less than the high-frequency current in the same phase as is shown in Figs. 9 and 10.

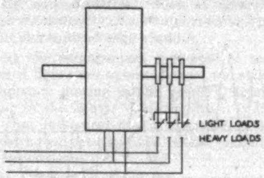

Fig. 11—A Suggested Connection by Which Operating Characteristics Might be Improved

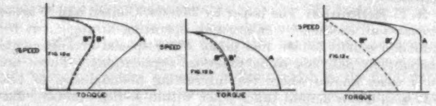
Conclusions

When the practical value of the connection is considered it can be seen that this connection increases the break-down torque approximately 100 per cent. The efficiency for heavy loads is higher than that of the same motor operated with its rings short-circuited. (See Figs. 3 and 5.) For light loads the efficiency of the motor with the rotor short-circuited is higher and the total excitation current is one-half or less depending upon the degree of saturation. When the machine is to be subjected to a wide range of loads it is possible to use a switching arrangement in the rotor that will short-circuit the rings when the load is light and connect the rotor and stator in parallel when the load is heavy. (See Fig. 11.)



A B C

Fig. 12

Curve *A*—Torque developed by motor when rotor and stator are paralleled
Curve *B*—Torque developed by motor with rotor short-circuited and power supplied to stator
Curve *C*—Torque developed by the motor with stator short-circuited and power supplied to the rotor

The advantages of this parallel connection are:

1. The rating of a given motor can be increased over what it would be if the rings were short-circuited.
2. Initial cost of motor required to drive a given load will be less and with the suggested switching arrangement smaller motors may be utilized giving the additional advantages.
3. The no-load losses may be made smaller.
4. The all day efficiency of the motor when subjected to a wide range of loads will be higher than that of a larger motor operating with its rings short-circuited.

The tests made on the machine as a motor and as a generator indicated two disadvantages of the parallel connection. The machine was noisy and the exciting current was high. This noise might be eliminated by special designing.

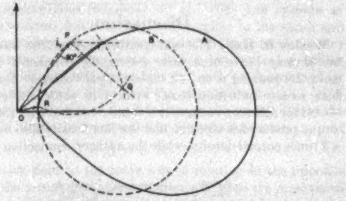


Fig. 13—Construction of Current Locus Diagram

Due to the super-imposed fluxes rotating in opposite directions the iron of the motor was saturated as is indicated in Fig. 14. This difficulty could be minimized by a special design.

It is possible to operate a wound rotor induction motor with its rotor and stator paralleled when ratio is not 1 to 1, by connecting the low-voltage rotor to the high-voltage line through an auto-transformer. The behavior of the machine under these conditions should be better than when no transformer is used, since the transformer will by-pass part of the low-frequency current that ordinarily would flow through the supply transformers.

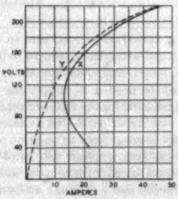

Fig. 14

Curve X—No-load current taken by the machine at different voltages with its rotor and stator paralleled
Curve Y—Estimated saturation curve

By designing the machine so that the rotor and stator phases have the same constants it is possible to obtain speed torque curves as shown in Fig. 12A, the total torque being the sum of the action and reaction. By putting resistance in each phase a characteristic can be obtained as in Fig. 12B. If either the rotor or stator are designed with a high resistance and those of the other element with a low resistance it is possible to obtain a total characteristic as shown in Fig. 12C, obtaining both high starting torque and also good regulation.

The effects of the low-frequency currents on the behavior of the line will depend to a certain extent on the ratio of the motor rating to the rating of the transformers supplying the load. It is obvious that if this ratio is large the efficiency might be reduced.

Discussion

Wesley B. Hall: The same performance as the authors obtained may be secured from a normally connected induction motor by running it on $\sqrt{2}$ times normal voltage. This can be done to any induction motor even if its rotor and stator are wound for different voltages or if it has a squirrel-cage rotor. The torque produced is uniform, and the flux density also uniform at $\sqrt{2}$ times normal density, while the authors' connection produces a torque pulsating periodically from zero to twice load torque, and a flux density pulsating from zero to twice normal density. The performance, losses, and efficiency are in general the same. A transformer may be needed to supply the increased voltage, which may not be required for the authors' scheme.

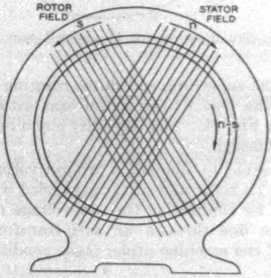

Fig. 1

With the rotor and stator paralleled as described in the paper, the air gap flux may be considered as made up of two components; a field set up by the stator, which will be of normal value and rotate at synchronous speed with respect to the stator, cutting the rotor at slip speed; and a field set up by the rotor, of equal value, which will rotate at synchronous speed with respect to the rotor and cut the stator at slip speed. Each of these fields will be of uniform constant value. This is shown in Fig. 1, where *n* indicates synchronous speed, *s* indicates slip speed, and *n-s* indicates rotor speed.

If the load on the motor is twice normal torque, it may be considered that the field produced by the stator carries normal torque and the field produced by the rotor carries an additional normal torque (although it will be shown later that this involves only the average value of a pulsating torque). Then the stator carries normal current at line frequency to maintain its own field and carries an additional normal current at slip frequency caused by the rotor's field. The true stator load current is the sum of these components and is shown in Fig. 2. The r.m.s. value of this sum is, of course, $\sqrt{2}$ times normal current in the stator winding. Similarly the current in the rotor winding is of exactly the same character and has an r.m.s. value of $\sqrt{2}$ times normal. This is the same value as would be present if the motor were normally connected and carrying twice normal torque on $\sqrt{2}$ times normal voltage. The similarity exists at all loads, so that for the two methods of connection the I^2R losses are equal, the efficiencies are the same, and the slips alike for any given load, neglecting differences in exciting currents.

The torque obtained by the authors' connection, however, is not the uniform sum of two uniform torques obtained from these two uniform rotating fields. The fields are periodically aiding or opposed, so that the resultant air gap flux is periodically zero or twice normal, at a frequency equal to line plus slip frequency, as may be seen by an inspection of Fig. 1. This result is shown in Fig. 3. When the fields are opposed the torque is zero, when aiding, it is twice load torque (four times normal in the specific case assumed). The periodic occurrence of twice normal flux density calls for very large magnetizing current, and the torque pulsation causes very evident vibration.

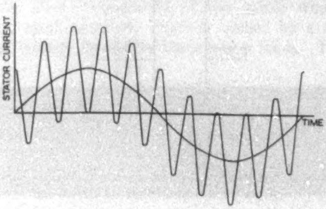

Fig. 2

The average value of torque equals the sum of the individual torques of the two component fluxes (twice normal in the case assumed).

R. E. Hellmund: The paper by Messrs. Conrad and Warner discusses an exceedingly interesting operating arrangement for induction motors, which like many other special arrangements undoubtedly will find some practical applications. There are other cases known where the interesting phenomenon of two induction motor actions takes place within a single motor. Examples of this are the various internal cascade arrangements and the operation of an induction motor with a single-phase secondary, which is equivalent to an internal cascade arrangement. To my knowledge, however, the particular arrangement described in the paper has not been covered previously in literature.

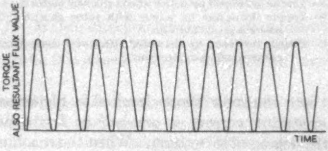

Fig. 3

Like many other special arrangements, the one covered in the paper probably will not find application for general purpose work because the same results can usually be obtained with the ordinary induction motor. This is evident from the following simple considerations. In the proposed scheme, double full-load torque, for instance, can be obtained by having a full-load current of slip-ring frequency superimposed upon full-load current of line frequency in each member. This means twice the full-load losses, because with two currents of different frequency superimposed, the losses are equal to the sum of the losses caused by the individual currents. On account of the superimposition of the two fields in the core portions, the maximum magnetic densities, however, are doubled. This, of course, will mean correspondingly high core losses and perhaps difficulties with noise, etc. If, on the other hand, the same motor were operated with 41 per cent higher voltage and 141 per cent load current, it would also give twice the output with twice the copper losses and only 41 per cent increase for the core densities. Such an arrangement would further obviate the necessity of a wound rotor and permit the use of the much simpler squirrel-cage winding.

In employing the arrangement suggested in the paper care must be taken if lights are operated from the same circuit, because low frequency flowing in the primary circuit is likely to cause flickering of the lights. This condition is similar to that obtained with an induction motor operated with single-phase secondary, which, except for this reason, might have found more general application.

Although for the reason stated the general application of the proposed arrangement is unlikely, it may nevertheless be useful in special cases, as, for instance, where speed torque characteristics as shown in Fig. 12c are desirable, and therefore the publication of the results obtained by the authors should be considered a welcome contribution to the art.

C. L. Fortescue: In dealing with rotating apparatus, by the method of symmetrical coordinates, the usual convention is to consider all phase sequences with reference to the stator. With this convention a symmetrically-wound induction motor running at normal slip will have only positive sequence currents in both stator and rotor. The same motor when driven above synchronous speed will have positive phase sequence currents in the stator and negative phase sequence currents in the rotor. Analytically this is taken care of by the fact that the negative phase sequence currents and e.m.fs. in the rotor are conjugates of the positive phase sequence quantities that appear in the analysis and which have negative indexes. The analytic method has no discontinuities but the solution is obtained, partly in terms of positive sequence quantities having the conventional positive indexes and partly in terms of positive sequence quantities having negative sequence indexes which in the final statement of the solution may be replaced by their conjugate negative sequence equivalents with positive indexes.

In dealing with problems in which the rotor is coupled with the primary circuit inductively or conductively the phase sequence relations of the motor with respect to the primary circuit must be considered with respect to these conventions, in order to obtain the correct analytical solution.

In the present problem from the standpoint of the stator and the circuit connections thereto the circuit connections to the rotor must be made negative sequence in order to give the same direction of rotation. Therefore, in the rotor the primary currents will be negative sequence as far as the motor reactions are concerned and the resulting secondary currents will likewise be negative sequence. But whereas the primary current in the circuit will be positive sequence for both stator and rotor, the secondary currents will both be negative sequence with respect to the primary circuit.

$S' \check{I}_{a1}$ is the positive sequence system of currents in the stator
$S^2 \check{I}_{u2}$ is the negative sequence system of currents in the rotor
$S^2 \check{I}_{a2}$ is the negative sequence system of currents in the stator
$S' \check{I}_{u1}$ is the positive sequence system of currents in the rotor

The equations of the induction motor operated with both primary and secondary connected to the same source of power are:

$$S' \check{E}_{a1} = S' \left\{ (R_a + j\omega_0 L_a)\, \check{I}_{a1} + j\omega_0 M \check{I}_{u1} e^{\,j(\omega_0 - \omega_1)t} \right\}$$

$$\begin{aligned} O &= S^2 \left\{ (R_a + j\omega_1 L_a)\, \check{I}_{a2} + j\omega_1 M \check{I}_{u2} e^{-j(\omega_0 - \omega_1)t} \right\} \\ O &= S' \left\{ (R_u + j\omega_1 L_u)\, \check{I}_{u1} + j\omega_1 M \check{I}_{a1} e^{-j(\omega_0 - \omega_1)t} \right\} \\ S^2 \check{E}_{a1} &= S^2 \left\{ (R_u + j\omega_0 L_u)\, \check{I}_{u2} + j\omega_0 M \check{I}_{a2} e^{\,j(\omega_0 - \omega_1)t} \right\} \end{aligned}$$

To simplify the problem assume $R_u = R_a$, $L_u = L_a$, then $I_{a1} = I_{u2}$ and $I_{a2} = I_{u1}$. The slip frequency is given by ω_1 and the synchronous frequency by ω_0. The two systems of primary currents, that is to say those supplied to the stator and rotor respectively, are entirely unrelated in the induction motor circuits as they are throughout without any mutual coupling. The two fields will be independent and each be determined by the impressed e.m.f., $S'\check{E}_{a1}$ as if the other did not exist. If B be the maximum value of the induction in the air gap due to the stator field, it may be represented by the rotating vector

$$S' \check{B} = S' B\, e^{\,j\omega_0 t}$$

The rotating field to the rotor will be rotating in the opposite sense to the actual mechanical rotation and since the mechanical rotation is $e^{j(\omega_0 - \omega_1)}$ the actual rotation of this induction in the air gap will be $e^{-j\{\omega_0 - (\omega_0 - \omega_1)\}}$ or $e^{-j\omega_1}$. Its value will also be B the same as for the stator so that the total induction will be

$$B\,(e^{j\omega_0 t} + e^{-j\omega_1 t})$$

So that in less than every complete cycle there will be a doubling up of the induction.

For the same output the heating due to copper loss is very much reduced. To get at this let us take I_a as the normal full load current when the machine is operating in a normal induction motor. We may assume the I_u is approximately equal to I. Then we shall have

$$I^2R \text{ loss} = (I_a^2 + I_u^2)\, R_a = 2I_a^2 R_a$$

Assume the two-winding scheme, and let the two currents supplied by the primary be mI_a, mI_u, etc. Then

$$I^2R \text{ loss} = 2\,(m^2 I_a^2 + m^2 I_u^2)\, R_a = 4m^2 I_a^2 R_a$$

For the same loss we have

$$4m^2 I_a^2 R_a = 2I_a^2 R_a$$

and therefore

$$m^2 = \frac{1}{2}$$

$$m = \frac{\sqrt{2}}{2} = 0.707$$

The current that may be supplied by the primary circuit to give the same I^2R loss will therefore be 41.4 per cent higher than for the straight induction motor. That is to say, its output for the same copper loss will be increased 41 and a fraction per cent.

To offset this the induction is doubled though the actual iron loss will not be so greatly increased in each element by the doubling of the induction but the rotor iron loss and the stator iron loss will have approximately the same magnitude, so that we may say that the iron loss for the same applied voltage will be approximately double that in the regular induction motor.

Some Considerations in the Design of Damper Windings for Synchronous Motors

BY C. C. SHUTT*
Associate, A. I. E. E

***Synopsis.**—As the application of synchronous motors is extended to include more specialized fields, the design of damper windings for special starting performance becomes more of an exact art. Methods have been presented before the Institute by which the starting performance can be determined with good accuracy. The purpose of this paper is to present certain possibilities and limitations of the performance which may be obtained by variation of the damper winding design.*

For purposes of consideration, damper windings are arbitrarily classified as low reactance and high reactance types. It is pointed out that low reactance damper windings are well suited to give a high ratio of torque to kva., especially during the initial part of the starting period. Many other types of performance, including a fairly uniform torque over the starting period or, a low starting torque with high pull-in torque—all with a relatively low kva. can be obtained with high reactance windings.

INTRODUCTION

THE constant effort of the designers of synchronous motors to improve the starting characteristics of their machines has led to marked advances in the art of predetermining their performance. Putman[1] and Linville[2] have given methods of calculating the performance of the motor throughout the entire starting period. By their use the designer may calculate the starting performance with reasonable accuracy provided, first, that he can calculate the machine constants correctly, and second, that he has an appreciation of the possibilities and limitations of the various combinations of these constants. It is the purpose of this paper to point out certain aspects of this second condition of successful design.

MACHINE CONSTANTS

For purposes of comparison, the machine constants may be classified as stator reactance (x_1) and resistance (r_1), damper winding reactance (x_b) and resistance (r_b), total rotor reactance (x_2) and resistance (r_2) and the magnetizing admittance (H). Often the individual damper bars do not all have the same reactance and resistance. Putman used an equivalent reactance and resistance for the damper circuit, in which the constants of the individual bars are combined into the constants of a damper winding made up of equivalent bars. Linville reduced the motor circuits to an equivalent network, placing each bar with its individual constants in a separate branch.

In this paper all constants are referred to the stator and expressed in per cent.

CHARACTERISTICS OF DAMPER WINDINGS

A good criterion for the best starting performance for a synchronous motor appears to be that the motor shall develop the required torque throughout the starting period with the lowest kva. that can be obtained without impairing the operating characteristics at synchronous speed.

The design of special damper windings for induction motors has been studied for years and probably most of the practical combinations have been used in them. In studying the problem of starting windings for synchronous motors, many of the steps of the induction motor designers doubtless are retraced.

Types of Windings. For the purpose of discussion, it is convenient to divide damper windings arbitrarily into two classes. The first is called "low-reactance windings." This includes all windings which are made up of round or rectangular bars of such size that skin effect has only a negligible effect on the distribution of the current in the bar. Such windings are so arranged in the pole head that the ratio of specific permeance to effective specific resistance of the winding as a whole is only slightly affected as the motor comes up to speed. The second class is called "high-reactance windings." This includes all forms of double deck windings, such as those having two distinct bars placed one over the other and all windings made entirely or in part of L bars or inverted T bars as well as plain rectangular bars of such a shape and material that they are subject to an appreciable skin effect. Moreover, the second class includes all single deck windings which are so arranged that the characteristics of the winding change noticeably as the motor comes up to speed.

Low-Reactance Windings. Most of the ordinary single deck damper windings are of the low-reactance type, although it will be shown in Appendix III that certain of them actually have a considerable change in characteristics as the motor comes up to speed.

In order to obtain the highest ratio of torque to kva. throughout the starting period, it is necessary to have the rotor circuits of high resistance and low reactance. Very high-resistance damper windings have the serious practical objection that they produce low torque at the higher speeds unless the motor has a low stator reactance. This difficulty becomes quite marked in low-speed motors. However, low-reactance

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

damper windings are well suited for low-speed motors with 40 to 50 per cent pull-in torque accompanied with a starting torque as high as 75 per cent. Higher torques with approximately the same ratio of pull-in to starting torque can be built with an increase in frame size. Most high-speed motors will produce 100 per cent pull-in torque with 150 to 175 per cent starting torque with low-reactance dampers.

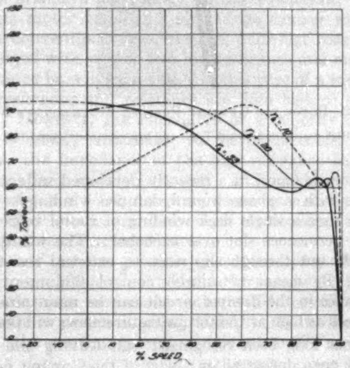
B



C

FIG. 1—EFFECT OF CHANGE IN DAMPER WINDING RESISTANCE ON TORQUE 2,000-HP., 150-R.P.M., 100 PER CENT POWER FACTOR SYNCHRONOUS MOTOR

A. Field open
B. Field closed through normal starting resistor
C. Starting resistor varied in same ratio as damper winding resistance

The effect of changing the damper winding resistance is shown in Fig. 1. Fig. 1A shows the case with the field open. The effects are the same as with an induction motor. Fig. 1B shows the same conditions except with the field winding closed through a starting resistor. It will be noted that the curve with the lowest resistance has the highest maximum value. This is because the maximum of the torque from the damper winding for this condition coincides most nearly with the maximum of the torque from the field winding. The effect of the field winding has been covered in a previous paper.[1] Fig. 1C shows as a matter of interest the results obtained when the starting resistor is varied in the same proportion as the damper winding resistance.

The per cent starting current for these cases is shown in the following table:

FIG.	1A	1B	1C
$r_b = 0.10$	360	400	400
$r_b = 0.20$	320	370	370
$r_b = 0.30$	260	320	320

An increase of the damper winding reactance decreases the torque at all slips. Probably most designers of synchronous motors have noted that increasing the damper winding reactance for a given value of resistance in some cases results in an actual increase in starting kva. The reason for this becomes apparent upon examining an approximate equation for starting current which was derived originally for the induction motor. The equation is:

$$I = \frac{\sqrt{1 + 2Hx_2}}{Z_0}$$

where Z_0 is the total impedance of the motor. Differentiating this expression with respect to x_2, it is found that the current has its maximum value when the following relation is fulfilled:

$$X_2 = \frac{-\frac{1}{H} + \sqrt{\left(\frac{1}{H}\right)^2 - 4\left(\frac{x_1}{H} - x_1^2 - r_0^2\right)}}{2}$$

where r_0 = sum of stator and rotor resistance.

An excellent example of a low-reactance winding in which a high ratio of torque to kva. is maintained at all times is found in a recently developed salient-pole motor with a phase wound damper winding.[4] This motor uses a single deck winding of round bars with a low permeance slot over each bar. The winding is brought out through slip rings to external resistance grids. By means of suitable control equipment, the resistance in the damper circuit can be maintained at all times as high as the torque requirements will permit.

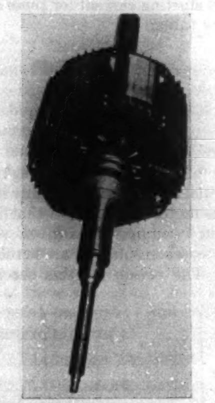


FIG. 2—ROTOR FOR GENERAL PURPOSE SYNCHRONOUS MOTOR

High-reactance inverted T bar and low-reactance round bar

It has long been recognized that leaving the field circuit open during all or a part of the starting period is an effective means of increasing the rotor circuit resistance and decreasing its reactance. Recently a number of applications calling for a particularly high ratio of torque to kva. has been filled with motors which had the field circuit open during the greater part of the starting period. Large and medium size slow-speed motors can be built readily for open field starting. They may be excited from standard 125 or 250-volt circuits by the use of a field sectionalizing switch mounted on the rotor.[4] Such switches have been successfully applied to low-speed motors both with a normal single cage winding and with the phase-wound damper. In high-speed motors of small and medium size, it has been found more convenient to use reduced voltage excitation, so that the voltage across the rings at starting will be kept within the limits of a reasonable amount of insulation on the field coils, the collectors and the control equipment. The reduction of kva. by the use of open field varies from 20 to 30 per cent in high-speed motors and from 8 to 15 per cent in the low speed. These kva. reductions are accompanied by an increase in starting torque of from 3 to 15 per cent.

An example of the possibilities of a single-cage, high-resistance, low-reactance damper winding is found in a 250-hp., 900-r.p.m., 100 per cent power factor motor for driving a hammer mill. The rotor was designed for low reactance. The motor was built for open field starting and tested 245 per cent starting torque with 110 per cent pull-in torque and 425 per cent starting kva.

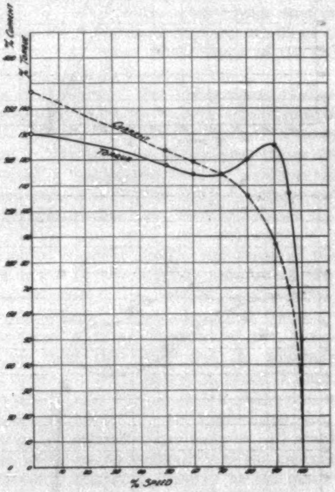

FIG. 3—SPEED-TORQUE AND SPEED-CURRENT CURVES FOR GENERAL PURPOSE TYPE OF SYNCHRONOUS MOTOR

250 hp., 900 r.p.m., 80 per cent power factor

Where a high ratio of torque to kva. is required, especially during the early part of the starting period, and where the starting torque itself must be high with a relatively low kva., low-reactance damper windings are well suited.

High-Reactance Windings. It is well recognized that to get any appreciable change in the effective resistance of any type of a double deck damper bar it is necessary for at least a portion of the material of the bar to be of low resistance. In high-speed, high-torque motors, where the damper winding must furnish a major portion of the impedance to limit the starting current, a straight double deck winding defeats its own purpose. If its reactance is high enough to limit the starting current, it is apt to be low in starting torque. And if the resistance of the winding is high enough to contribute materially to the impedance of the machine, it probably will not have enough decrease in resistance at the higher speeds to give the required torque.

Double deck windings of the conventional induction motor type, with two distinct bars placed one over the other, have been used rather commonly on slow-speed synchronous motors which require nearly a uniform torque throughout the starting period. A recent A.I.E.E. paper[6] discusses applications of this type and presents a set of performance curves for a rubber mill motor showing 120 per cent starting torque and 100 per cent pull-in torque. Many rubber mill applications require a somewhat higher starting torque with the same pull-in torque.[5] On these latter applications motors with the simpler low-reactance winding give good performance.

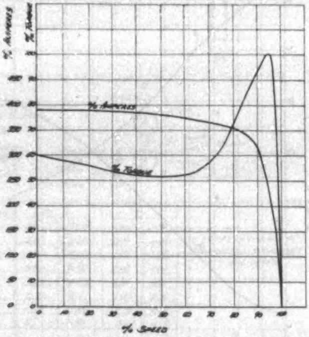

FIG. 4—SPEED-TORQUE AND SPEED-CURRENT CURVES FOR A 700-HP., 900-R.P.M., 100 PER CENT POWER FACTOR SYNCHRONOUS MOTOR FOR CENTRIFUGAL PUMP DRIVE

One field in which high-reactance rotors may be used to advantage is the general purpose class of motors and those of somewhat higher horsepower rating, which usually have general purpose characteristics. These motors require 100 per cent pull-in torque and only a little higher starting torque. Due to the usual small physical size of these motors, it has been found that bars of an L or inverted T section are well suited. The use of a few high-reactance bars, combined with low-reactance bars in the same pole head, presents no serious manufacturing difficulties and gives sufficient impedance at the start to limit the current, yet low enough resistance at low slips to give the required pull-in torque. The constants of such a winding are given in Appendix II. Fig. 2 shows an 8-pole rotor for a general purpose motor of this type.

Curves of the tested starting performance of a 250-hp., 900-r.p.m., 80 per cent power factor motor are shown in Fig. 3.

An interesting example of the possibilities of special forms of high-reactance rotors is found in the design of high-speed motors for centrifugal pump and blower drive. This is a good example of an application where a low torque per kva. is quite acceptable. The present day requirements are at least 100 per cent pull-in torque with 50 to 60 per cent starting torque and the starting current between 400 and 450 per cent.

One solution of the problem which has been quite successful is the two winding motor described in a recent A.I.E.E. paper.[6] This method often gives the required starting performance from motors of practically standard design. However, there are cases, especially with small high-voltage motors, where it is difficult to obtain the required number of parallels. And the control equipment must include an auxiliary contact or breaker for closing the second half of the winding.

For this reason, a high-speed motor with a simple type of high-reactance rotor and a normal, high efficiency stator has been developed, which permits the use of standard full voltage starting equipment.

This motor employs a single-cage damper winding of the conventional type, except of quite high resistance, combined with one or two low resistance and medium reactance bars in each pole. In this type of a winding, the resistance and reactance are both high at standstill. However, the impedance of a majority of the bars is mostly resistance. As the motor comes up to speed, the impedance of the high-resistance bars remains approximately constant. The impedance of the low-resistance bars, however, decreases materially at the higher speeds, and thus effects the necessary reduction in total rotor impedance.

A set of test curves on such a motor rated at 700-hp., 900-r.p.m., 100 per cent power factor is shown in Fig. 4.

These tests were made with the field circuit closed through a proper starting resistor. With the field open, the starting current is reduced to 275 per cent, with a slight increase in starting torque.

As the applications of synchronous motors become more specialized, there will doubtless be a marked improvement in the results obtained from special, yet simple, forms of high-reactance damper windings.

ACKNOWLEDGMENT

The author acknowledges the aid of Mr. M. R. Lory in calculating several of the examples given in this paper.

FIG. 5—CHARACTERISTICS OF RECTANGULAR BARS

A. Resistance σ = ohms per cu. in. × 10^6
B. Reactance ϕ = specific permeance per cm length

Appendix I

CHARACTERISTICS OF VARIOUS TYPES OF DAMPER BARS

The constants of a number of types of damper bars in common use are presented here for reference and comparison. Much of the material has been presented before. See Fig. 7 for reference to dimension letters.

1. Round Bar. The resistance of the round bar is ordinarily determined by its cross section and the specific resistance of the material without reference to skin effect. Mr. Fechheimer[7] showed that the permeance is

$$1.26 \left[0.62 + \frac{d}{W} \right]$$

The figures were obtained by integration in polar coordinates based on flux lines going straight across the round slot. Careful flux plots have later shown the value of the constant inside the bracket to be 0.66 instead of 0.62.

2. Square Bar. In this class are included all bars of square or approximately square cross section. Here, also, the resistance usually may be calculated without regard to skin effect. The permeance is given by the well known expression

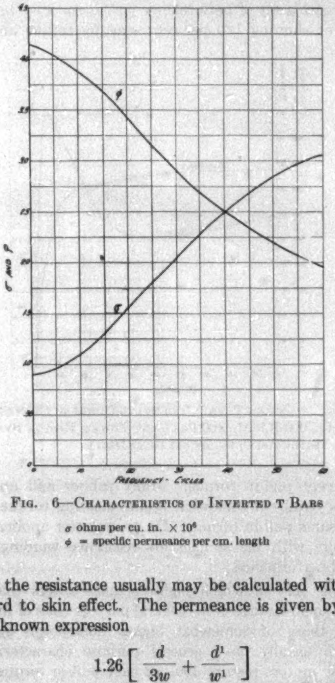

FIG. 6—CHARACTERISTICS OF INVERTED T BARS

σ ohms per cu. in. × 10^6
ϕ = specific permeance per cm. length

$$1.26 \left[\frac{d}{3w} + \frac{d^1}{w^1} \right]$$

It is apparent at once that a square bar has a better power factor than a round one for the same resistance.

3. Rectangular Bar. In determining the constants of a rectangular bar the displacement of the current in the bar itself at the higher frequencies must be taken into account. The expressions may be conveniently derived by the use of integral equations. A more general formula has already been presented[1] which reduces for a rectangular bar to

$$Z = \frac{r(A + jA)}{ab}\left[\frac{\cosh 2A \cos 2A + j \sinh 2A \sin 2A}{\sinh 2A \cos 2A + j \cosh 2A \sin 2A}\right]$$

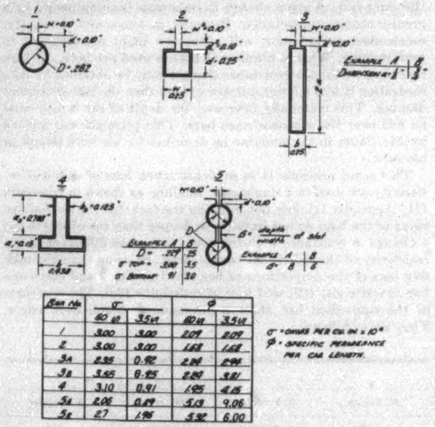
where

$$A = 2\pi a \sqrt{\frac{f}{r}}$$

r = specific resistance—absolute units

f = frequency

The impedance Z will be given in absolute units. The expression does not include the permeance of the slot above the bar. A set of curves covering various depths of 1/4 inch wide bar is shown in Fig. 5A and 5B.



Bar No	σ		φ	
	60 ∿	35 ∿	60 ∿	35 ∿

5B	2.7	1.96	5.92	6.00

FIG. 7—CHARACTERISTICS OF SEVERAL COMMON BARS

4. Inverted T Bars. The theory of the calculations for the inverted T bar has been presented in a previous paper.[1] The impedance formula in hyperbolic notation is

$$Z = \frac{r(A + jA)}{b_2}\left[\frac{R \cosh (S+jS) - \cosh (D+jD)}{R \sinh (S+jS) - \sinh (D+jD)}\right]$$

where $R = \dfrac{b_1 + b_2}{b_1 - b_2}$, $s = A\,(a_2 + a_1)$, $D = A\,(a_2 - a_1)$.

Fig. 6 gives a set of curves for a copper bar of the dimensions shown in Fig. 7.

5. Double Deck Bar. Perhaps the best known form of double deck bar for induction motors is that consisting of two bars, one above the other. They have been used to a certain extent on synchronous motors, although the limited depth of pole head presents a handicap to their application.

In general, bars of this type are of such a shape and size that the skin effect in the conductor itself is negligible. The impedance of the type shown in Fig. 7 is given by

$$Z = \frac{r_a\, r_b - 105\ w^2(1+G) + jw\ [r_a(24.3+12.6G) + r_b\ 8.32]}{r_0 + jw\ 4\pi\ (1.025 + G)}$$

where

r_a is resistance of top bar in absolute units per centimeter length

r_b is resistance of bottom bar in absolute units per centimeter length.

$r_0 = r_a + r_b$

$w = 2\pi f$

G = ratio of depth to width of slot between bars.

The impedance Z is given in absolute units. It does not include the permeance of the slot above the bars.

The above list is not inclusive of all types of bars in use, but fairly covers the range of common practise.

Fig. 7 shows sketches of the various types of bars together with a comparison of their characteristics.

Appendix II

CHARACTERISTICS OF A COMBINATION OF INVERTED T BARS AND ROUND BARS FOR A GENERAL PURPOSE MOTOR

In this appendix examples are given of the constants which can be obtained by the use of high and low reactance bars in the same pole. The desirable characteristics are a high impedance with fairly high power factor at the start and an appreciable decrease in resistance as the motor comes up to speed. A sketch of a pole using 2 high-reactance bars of the inverted T type combined with 4 low-reactance bars is shown in Fig. 8.

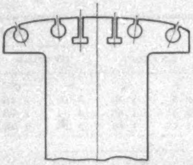

FIG. 8—POLE PUNCHING FOR A GENERAL PURPOSE MOTOR

Instead of handling each bar separately in calculating the starting performance, it is convenient to find the resistance and permeance constants of an equivalent bar of such characteristics that the winding may be considered to consist of 6 (in the case of Fig. 8) such equivalent bars per pole. The impedance of the equivalent bar may be found by multiplying the actual impedance of all bars in parallel by the number of bars.

The following table gives the specific resistance and specific permeance of the equivalent bar for the pole shown in Fig. 8 with various resistance materials in the round bars. The inverted T bar is copper in all cases. The equivalent bar will have the same area as one of the inverted T bars.

		⊥ bar				Equivalent bar			
Round bar		60 cycles		3.5 cycles		60 cycles		3.5 cycles	
σ	φ	σ	φ	σ	φ	σ	φ	σ	φ
1.87	2.51	2.07	2.89	0.831	4.09	2.10	2.62	1.45	4.23
2.84	2.51	2.07	2.89	0.831	4.09	2.84	2.69	1.74	5.34
5.50	2.51	2.07	2.89	0.831	4.09	4.20	3.08	2.08	7.23
12.82	2.51	2.07	2.89	0.831	4.09	6.21	4.68	2.44	9.70

σ = resistance per cu. in. × 10^6
φ = specific permeance per cm. length.

It will be noted that the highest resistance round bars give the greatest decrease in resistance as the motor comes up to speed. A 250-hp., 720-r.p.m. motor using the last combination listed calculated 14.8 per cent damper circuit reactance and 17.3 per cent resistance at standstill.

Appendix III

CONSTANTS OF SINGLE-CAGE WINDING ON ROUND BARS

In some cases where the winding is made of round or square bars, all the same size, the slots above the bars are deeper at the center of the pole than near the tips.

Consider a pole with five 3/8 inch round bars. The slots over the middle 3 bars are 3/16 inch deep by 1/8 inch wide and over the two end bars they are 1/16 inch deep by 1/8 inch wide. In case it is necessary to use bars of different materials to meet the necessary resistance, an appreciable change of constants may occur as the motor comes up to speed. For bars all of the same material, the change is quite small. Three examples are illustrated in the following table:

				Equivalent bar			
Center bars		End bars		60 cycles		3.5 cycles	
σ	φ	σ	φ	σ	φ	σ	φ
5.5	2.72	5.5	1.46	5.56	2.16	5.51	2.21
1.98	2.72	5.5	1.46	3.04	2.93	2.66	3.05
5.5	2.72	1.98	1.46	3.30	2.08	3.18	2.12

Discussion

M. R. Lory: Synchronous motors are being applied to a great variety of applications which differ widely in starting requirements. The popularity of full-voltage starting with its cheaper and simpler control has increased the importance of limiting the kva. drawn by the motor during the starting period. The problem of the designer is to meet the torque requirements of the load and still keep the current drawn from the line to a minimum. In his paper, Mr. Shutt has given a comprehensive summary of the various means by which the designer can accomplish this result.

In Fig. 7 and Appendix I, Mr. Shutt has given the constants for several types of damper bars including two double-deck arrangements. Mr. Shutt pointed out the difficulty of using double-deck windings where the depth of pole head is limited. As a matter of interest, I have calculated these two examples with the two bars in parallel but in separate slots, making the permeance of the slot above each the same as the permeance which it has in the arrangement given in Fig. 7. Calculated on the same basis, the values of the constants for the two bars are as follows:

	σ		φ	
	60 cycles	3.5 cycles	60 cycles	3.5 cycles
5-A	1.83	0.713	3.62	8.16
5-B	2.66	1.95	3.83	4.93

In many cases the above characteristics are not as desirable as those given by the conventional arrangement with both bars in the same slot. A given change in resistance is accompanied by a greater change in reactance. However, in some cases the simpler mechanical construction will offset the slight disadvantage in performance. When a number of bars is used per pole, the high reactance of the low-resistance damper may be obtained by concentrating it into a fewer number of bars than the high-resistance damper. This materially decreases the depth of slot which must be put over the low-resistance bars. This principle was utilized by Mr. Shutt in the machine he describes for use with pumps or blowers.

This same principle is in evidence when bars of different resistivity are used in a single cage winding, as shown in Appendix III. Appendix III does not mention the fact that the slots above some of the bars do not have to be deeper than the others to get a change in resistance with frequency when the difference of the resistivity of the individual bars is large. So as an example, take five bars of the proportions of bar No. 1 of Fig. 7 and make one bar of resistivity 0.91 and four of resistivity 13.6. The constants of the equivalent bar show a pronounced double-deck effect. They are as follows:

σ		φ	
60 cycles	3.5 cycles	60 cycles	3.5 cycles
4.46	3.59	6.08	6.6

I believe that the formula for the value of X_2 for maximum inrush is more of theoretical interest than of practical value. I find that with the constants normally found in design this formula gives either negative values or positive values which are so small that they are below what would be obtained in a machine.

R. E. Hellmund: Mr. Shutt's paper is further evidence of the excellent progress which has continuously been made by American designers of synchronous motors in the development of motors suitable for the many commercial applications. As a result of such work, the American market has been kept free of the numerous more complicated and therefore less desirable excitation and phase-advancing schemes for induction motors which we find so extensively discussed and produced in Europe. In this country these various arrangements have been investigated and built experimentally, but it was found that economically the synchronous motor designs were always just one step ahead of anything which could be accomplished with the various possibilities of excitation of induction motors. By the use of the simplest design features and through painstaking design work, many desirable characteristics have been obtained with synchronous motors, and at the same time design proportions have been worked out which have resulted in very favorable cost comparisons with domestic induction motors and which for many years have been away ahead of any European synchronous motor designs which have come to my attention.

Part of the credit for keeping the more complicated induction motor arrangements off the American market is also due to the central station engineers through their permitting starting-current and kva. values in excess of those usually permitted in other countries.

These remarks may answer the question frequently raised as to why various exciter and phase-advancer schemes for induction motors have not been commercially exploited in this country.

C. C. Shutt: The intensive study of the starting performance of the synchronous motor has been carried on for a comparatively short time when compared to its predecessor in the alternating current field—the induction motor. The designer of synchronous motors can obtain a great amount of benefit from a study of what has been tried and adopted—or discarded—in the starting windings of induction motors.

In commercial design work the designer is somewhat handicapped by the fact that present methods of calculation, which accurately take into account the effects of the field winding, are rather laborious. It is expected that improvements will be made in the near future in the methods of calculating the starting performance.

In regard to Mr. Lory's comment on the practical value of the formula for the value of X_2 which gives the maximum inrush, an inspection of the equation as given in the paper will show that for high values of resistance X_2 may have an appreciable magnitude. In actual design work this "critical" value of rotor reactance will be noticed particularly on high-speed motors where the starting current must be limited largely by the impedance of the rotor. In these cases the damper winding resistance is often made quite high.

Mr. Hellmund's remarks are particularly applicable to the low-speed field. The operating advantages of the low-speed synchronous motors permit the use of many low-speed direct-connected motors in industrial applications which would otherwise require high-speed induction motors, which have relatively high full load power factor and efficiency, and reduction gears or belts.

Film Characteristics of Electrolytic Condensers

BY F. W. GODSEY, Jr.*
Associate, A.I.E.E.

***Synopsis.**—Electrolytic condensers of the film-forming type have some interesting characteristics which have never been satisfactorily explained. Extremely thin oxide or hydroxide films formed on the surface of the metal anodes seem insufficient in themselves to explain the complete action. Likewise, an electromotive equilibrium is insufficient to explain the action.*

A résumé of former research reveals a great deal of information of large practical value in building electrolytic condensers but little of value from a theoretical standpoint. Reviewing the prominent papers, it appears that aluminum has been the chief subject of discussion for condenser anodes. Such anodes show small leakage currents in selected electrolytes at low temperatures. Increasing voltage, temperature, or electrolyte concentration cause increases in leakage; the addition of impurities also has a deleterious effect.

The oxide-gas theory of rectification as applied to electrolytic condensers by Guntherschulze predicts changes in capacity for variations in pressure. Experiments do not substantiate the presence of gas. The oxide layer alone is unable to fulfil the necessary conditions found.

Electrolytic condensers with extremely low applied voltages show large variations in measured capacity from high-voltage measurements. The results indicate a film in which ion penetration plays a large part.

The presence of a film saturated with water as the dielectric overcomes a number of former obstacles, and lessens the necessity for the very thin films formerly assumed, due to the high dielectric constant of water.

* * * * *

ELECTROLYTIC condensers have been of general interest to electrochemists since 1855 when Wheatstone[1] presented a paper on the polarization of aluminum in electrolytes.

A number of metals possesses the property of forming on their surfaces protective coats when immersed in electrolytes. The skin formed is extremely thin normally; but if the metal is made electrically positive with respect to the electrolyte the thickness will increase until the layer is readily apparent. This film has a high electrical resistance, rising in some instances to several thousand megohms per square cm. of surface, the resistance remaining only as long as the metal is the anode in the electrolyte.

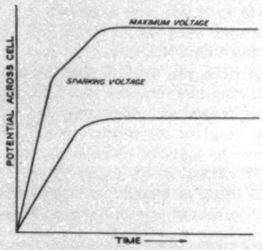

FIG. 1—THE FORMATION OF AN ELECTROLYTIC CONDENSER ANODE WITH CONSTANT CURRENT THROUGH THE ELECTROLYTE

Upper curve high current density, lower curve low current density

This film assumes the role of the dielectric in a condenser,[2] the plates of which are the metal on the one side and the electrolyte on the other.

The metals which form protective films in electrolytes include aluminum, antimony, bismuth, magnesium, zinc, niobium, vanadium, colombium, zirconium, tantalum, their alloys, and a number of other metals. These metals all can be used in electrolytic condensers. Copper and silver exhibit ionic valve action as opposed to the electronic valve action of film forming metals.[3]

The choice of electrolytes is narrow when aluminum is used as the electrode, but tantalum exhibits valve action in all electrolytes except hydrofluoric acid. The usual practise in selecting an electrolyte for aluminum is to choose the salt of a weak acid and a strong base which will nearest meet all specifications. A sufficient amount of free acid is usually added to the solution to insure an acid reaction to retard the precipitation of aluminum hydroxide.

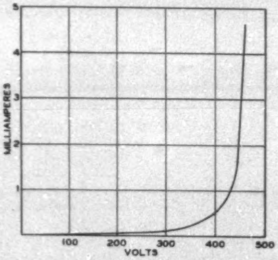

FIG. 2—LEAKAGE CURRENT OF 8-MICROFARAD CONDENSER FOR RADIO FILTER CIRCUITS, FORMED TO 450 VOLTS, 25 DEG. CENT.

If a strip of pure aluminum is made the anode in a suitable electrolyte and a constant current is caused to flow, the voltage across the cell will rise with increasing time as indicated by the curve of Fig. 1. The initial portion of the curve is straight, but as the voltage is raised, the rate decreases and abrupt bends appear in

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

the curves. Close examination will disclose a faint luminescence at the surface of the anode after the first bend; and upon further increases small sparks appear at the surface of the aluminum and finally heavy sparking takes place between the anode and the electrolyte and large current increases result from small increases in voltage. This maximum voltage varies widely under different conditions and it is known as the breakdown voltage; but the useful operating range of the condenser is below the first bend in the curve. The lower curve of Fig. 1 is for a lower forming current; in this case the maximum voltage is not approached.

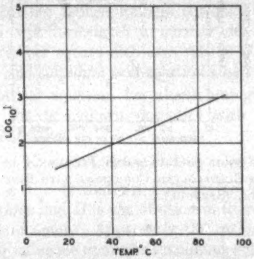

Fig. 3—Leakage Current of Aluminum Anode Plotted as a Log Function against Electrolyte Temperature. (Bairsto and Mercer)

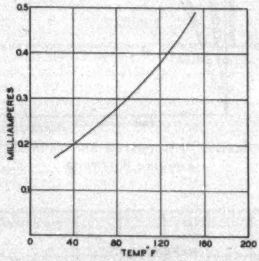

Fig. 4—Leakage Current of 8-Microfarad Aluminum Condenser with 350 Volts Impressed, for Different Operating Temperatures

Fig. 2 is the characteristic leakage current of an eight-microfarad aluminum condenser formed to 450 volts. The area of the anode is 72 square inches, and the solution is saturated sodium borate with the addition of sufficient boric acid to insure an acid reaction from the electrolyte. The leakage current of a condenser depends not only upon the voltage, but also the materials used and the operating temperature. The effect of temperature on the leakage current of aluminum is expressed by the empirical equation.[4]

$$I = A\epsilon^{\alpha T}, \qquad (\log_e I = \log_e A + \alpha T$$

where A is a constant, α is a constant dependent only on the equivalent weight of the anion in solution, and T is the temperature. When the current density is high the rise of current with temperature is more rapid than predicted. Fig. 3 shows the leakage of an aluminum anode plotted as a log function against temperature. The variation of film resistance with impressed voltage[5] is illustrated in Fig. 5 which shows clearly the asymmetrical characteristic of the cell.

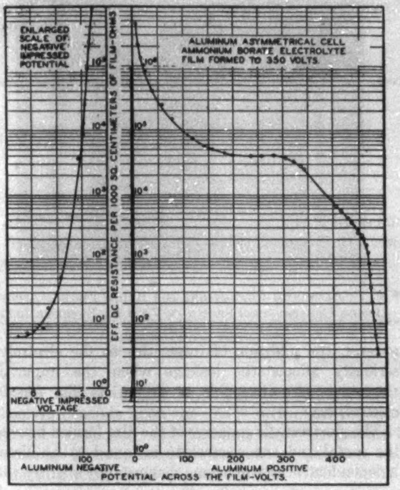

Fig. 5—Variations of Film Resistance with Impressed Voltage in Aluminum Electrolytic Condenser. (Siegmund)

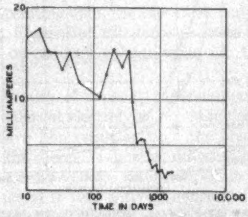

Fig. 6—Decrease in Leakage Current of Electrolytic Condenser with Time. (Siegmund)

After an anode has had high voltages applied the leakage currents are found to be slightly higher for normal voltage values upon reduction of the voltage. After a relatively short time has elapsed, practically the same values of leakage current are obtained. Over a long period of time condenser characteristics change appreciably,[5] particularly when the condenser is formed initially to a voltage different from the operating voltage, Fig. 6.

With metals that are soluble or slightly soluble in the electrolyte, leakage current may increase rapidly with concentration of the solution. Using aluminum as the anode, the addition of very slight amounts of chlorine will increase leakage current many fold. In general, the addition of impurities to the electrolyte seriously affects the leakage when the impurities themselves are incapable of acting as film forming electrolytes.

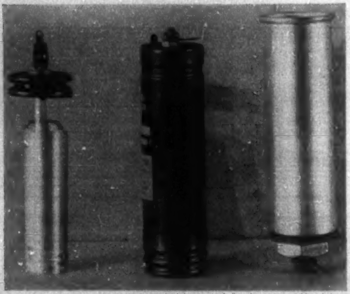

Fig. 7—Aluminum Condensers for Radio Filter Circuits. Anode Construction Shown in View on Extreme Left

The electrostatic capacity of the film formed between the metal and the electrolyte is found to be almost independent of the solution, changes only slightly with variations in temperature, and is inversely proportional to the voltage of formation of the anode, Fig. 8.

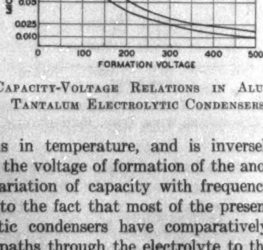

Fig. 8—Capacity-Voltage Relations in Aluminum and Tantalum Electrolytic Condensers

The variation of capacity with frequency is slight but due to the fact that most of the present forms of electrolytic condensers have comparatively long resistance paths through the electrolyte to the film, the effective capacity decreases with increases in frequency, Fig. 9.

The breakdown voltage of a condenser depends upon the electrolyte and the anode metal. An aluminum anode has been formed to 1890 volts.[6] The usual commercial aluminum condenser is formed to 500 volts. Tantalum condensers are formed commercially to 150 volts, with possibilities of units to withstand 600 volts. The other metals and alloys are not in general use and only a small number are suitable for commercial applications.

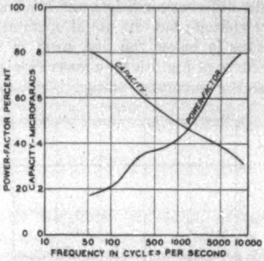

Fig. 9—Effect of Increasing Frequency on Effective Capacity of Electrolytic Condenser with High Resistance Electrolyte. (Sprague)

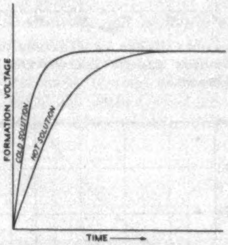

Fig. 10—Formation of Aluminum Anodes in Hot and Cold Forming Solutions

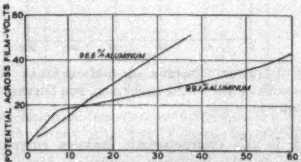

Fig. 11—Influence of Purity of Aluminum on Rate of Formation. Forming Current 0.078 Milliamperes per Sq. Cm. (Siegmund)

The rate of formation of a film varies widely under different conditions. In general the gradient of the curve in Fig. 10 is independent of the concentration of the electrolyte, and decreases considerably with increasing temperatures as indicated by the lower curve. The rate of formation in volts per second is almost directly proportional to the current density at high current densities, so that equal formation voltages are produced by equal quantities of electricity through the cell. Pure aluminum forms at a lower rate than impure aluminum, Fig. 11.

Commercial aluminum condensers formed to 450 volts approximately are formed in hot electrolytes; current densities range from 5 to 15 milliamperes per square inch. After the formation period, the condensers are given an aging period of two to eighteen hours to further reduce leakage current. Tantalum condensers will form with a current density of 15 milliamperes per square inch at a rate of 60 volts per minute in cold sulphuric acid solution.

An empirical equation for aluminum[6] gives a decrease in the breakdown potential with increasing ionic concentration,

$$V = (514.51 \log D\text{-}330) \text{ volts}$$

where V is the breakdown voltage for small ionic concentrations and D is the dilution in litres per gram equivalent of anion. Apparently the cation has very little or no influence upon the maximum voltage.

Table I compares the breakdown voltage of tantalum with that of aluminum in 0.1 N. solutions after 24 hours of formation.

TABLE I

Solution	Aluminum	Tantalum
Sodium chloride	— volts	390 volts
Oxalic acid	—	445
Potassium cyanide	275	520
Potassium permanganate	112	105
Ammonium chromate	122	147
Sodium silicate	445	540
Sodium sulphate	40	490
Ammonium citrate	470	550
Borax	480	540
Diamonium phosphate	460	575
Ammonium bicarbonate	425	525
Citric acid	536	605

Some metals will "form" in molten, water-free salts.[7] Aluminum will form to approximately 80 volts in molten potassium nitrate. However, the effective film thickness is found to be as high as forty times as much as in aqueous solutions for aluminum, and up to five times as thick for tantalum.

The maximum voltage is affected also by the nature of the anion. In case of anions containing metals, a specific maximum voltage is given by that anion for any stated concentration and the maximum is dependent upon the metal of the anion. Table II for tantalum in 0.05 N. solutions of chromium gives practically the same breakdown voltage in each case.[8]

TABLE II

Metal	Cation	Anion	Maximum voltage
Chromium	K	Cr_2O_7	131
		CrO_4	141
		$Cr(C_2O_4)_3$	136
		$Cr(CN)_6$	126
			133 Mean.

The following list of the specific maximum voltages applies for 0.05 N. solutions of the electrolytes,[8] Table III.

TABLE III

Pd	19.5	Cr	133	H	448
Pt	20	Ni	181	Bi	450
Rh	23	Sn	190	Hg	453
Au	24	Co	243	Cd	478
Ir	32	Cu	335	Al	660
Mn	46	W	363	Sb	435
Fe	84	Ag	422		

Only the metals seem to have a definite voltage but a few of the other elements seem to give fairly consistent results,[8] Table IV.

TABLE IV

Nitrogen	470	Silicon	490
Arsenic	465	Fluorine	505

After voltage is removed, the rate at which the film dissolves depends upon the anode metal and the electrolyte. Antimony and tantalum are very sensitive to current interruptions, but bismuth, magnesium, and aluminum films dissolve very slowly. With a reduction in thickness of the film there is also an increase in capacity. A condenser originally formed to a voltage higher than the operating voltage will gain capacity until it stabilizes at the new value of voltage, the time depending upon the condenser and the voltage difference. Capacities will increase more rapidly for condensers on reduced voltage when the temperature is high.

The uniformity of capacity measurements for films formed in different electrolytes preclude the possibility of an effective film resulting from the reaction of the metal and the anion. Likewise, different metals have different capacity-voltage ratios, which indicates that the anode metal is very actively concerned in the film structure with film thicknesses ranging from 10^{-6} to 5×10^{-4} cm.

The existence of a film on the surface has been questioned,[9] and due to the fact that chlor-ion concentrations destroy valve action in aluminum and also due to the fact that an amalgamated electrode of aluminum will not form a film, it has been proposed that an electromotive equilibrium exists.[10]

Interference measurements[11] of the thickness of films have given results of 5×10^{-6} to 5×10^{-4} cm. for aluminum. A method of removing the aluminum and leaving the film intact has been tried;[12] the thickness of these films as measured with a direct vision spectroscope was approximately 7×10^{-4} cm. Film thicknesses were also measured by computing the weight of anion deposited in the formation period by measuring the forming current in coulombs; and also by the increase in weight,[12] Fig. 12. By assuming a dielectric constant for the film equal to unity, the effective film thickness can be computed from capacity measurements and comparisons have been made for a number of anode metals and electrolytes,[13] Fig. 13.

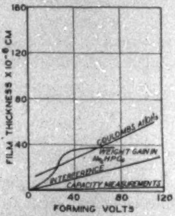

FIG. 12—FILM THICKNESS ON ALUMINUM ANODES AS MEASURED BY CAPACITY MEASUREMENTS, INTERFERENCE METHODS, INCREASE IN WEIGHT OF FORMED ANODE OVER UNFORMED ANODE, AND BY THE FORMATION CURRENT. (MOTT)

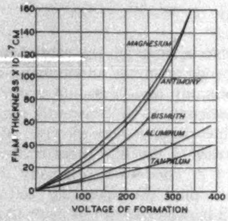

FIG. 13—RELATIVE FILM THICKNESS OF DIFFERENT METALS; DIELECTRIC CONSTANT UNITY. (GUNTHERSCHULZE)

Relative thickness of films for aluminum and tantalum in aqueous solutions and in fused, water-free salts are given in Table V.

TABLE V—RELATIVE THICKNESS AT 50 VOLTS AFTER 30 MINUTES FORMATION. (THICKNESS × 10^{-7} CM. FOR DIELECTRIC CONSTANT UNITY)

Electrolyte	Tantalum	Aluminum
Dilute aqueous	4.10	6.36
Pure sulphuric acid	6.69	10.65
Fused water-free		
NH_4NO_3	6.26	—
$KHSO_4$	6.98	13.10
$AgNO_3$	7.12	220.
$TlNO_3$	10.10	—
$LiNO_3$	7.93	—
$NaNO_3$	12.50	133
KNO_2	11.10	142
$K_2Cr_2O_7$	18.20	30

The electromotive equilibrium theory has been advanced as a complete explanation of the action at an anode surface;[10–14] evidence has also been presented for the presence of a film which forms when the aluminum is the anode and dissolves when the aluminum is the cathode.[15] However, oscillograms do not show such action during rectification, current passing immediately when the voltage reverses across the film. On high voltage rectifiers, the weight of the supposed aluminum hydroxide film which would have to be formed, dissolved, and reformed many times a second is prohibitive to such a theory. One investigator[16] was convinced by a microscopic examination of the luminous points, that they constitute an immense number of Wehnelt interrupters in parallel.

The first satisfactory theory accounting for alternating current rectification was advanced in 1902 by Guthe.[17] This was the oxide-gas film theory which proposed that a solid oxide or hydroxide film is formed, proportional in thickness to the formation voltage. Accompanying the oxide layer a thin film of oxygen formed on the solid film increases the leakage resistance. Rectification was attributed to the high mobility of free electrons when penetrating the films as compared to the relatively heavy and slow moving anions of the electrolyte. The electrons are able to easily penetrate the films even under very low accelerating fields, but the ions are not able to penetrate the oxide film deeply enough to reach the anode metal. Since there is an abundance of free electrons in the metal and none in the electrolyte, rectification will take place.

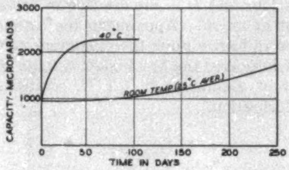

FIG. 14—ALUMINUM CONDENSERS OPERATED AT HALF OF THE FORMATION VOLTAGE. EFFECT OF TEMPERATURE ON THE RATE OF CAPACITY CHANGE. (SIEGMUND)

This theory has undergone considerable expansion. The gas layer was thought to carry the principal burden so far as voltage drop was concerned due to the low specific inductive capacity of oxygen; and the oxygen film was supposed to constitute the real capacity of the anode. Fig. 15 shows the relative thickness of the gas and oxide layers on an aluminum anode. This convenient mechanism was employed to explain many of the former discrepancies observed for electrolytic rectifiers and condensers. Guntherschulze[18] calculated potential gradients as high as 8,000 volts per micron in such very thin films.

In an experiment to detect the presence of gas,[18] an aluminum anode was formed to 400 volts, and the voltage was suddenly reduced to 4 volts. The calculated reduction in pressure was from 2,100 to 0.21 kg. per cm.^{2}; but instead of an expansion of gas and reduction in capacity, the capacity increased slightly. Fig. 16 is illustrative of the supposed arrangement of oxide layer and gas film adsorbed in the pores of the oxide film. Hydrostatic pressure applied to the electrolyte of rectifiers caused decreases in rectification.[19] Pressures up to 20 atmospheres were applied, and results indicated that the gas-oxide theory was correct.

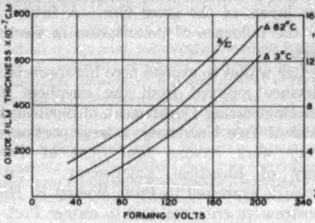

Fig. 15—Relative Thickness of Gas Layer Compared to Oxide Film on Aluminum Anode. (Guntherschulze)

An attempt was made by the writer to correlate the discrepancies found, and a condenser was constructed with provisions for applying pressure up to one hundred atmospheres. Both electrodes were of aluminum and of the same area of 350 sq. cm. The condenser was formed to 100 volts on a 60 cycle circuit, and oscillograms were made of the applied voltage and current at 80 volts 60 cycles for pressures ranging from atmospheric to 1,500 lb. per sq. in. The r.m.s. value of current was found to be 0.297 ampere in every case, and the oscillograms showed no change in current wave shape when sine wave voltage was applied.

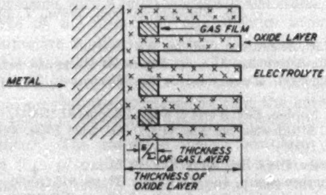

Fig. 16—Roughly Equivalent Structure of Film on Anode Showing Gas Layer in the Gross Film, and the Continuous Oxide Layer

If the experiments of Carman and Balzar[19] on the effects of increased pressure on rectification are discounted, the reduced voltage experiment of Guntherschulze and the writer's work with condensers under pressure both indicate that there is no gas film present. There may be oxygen present; but if so, it is undoubtedly present as an adsorbed gas in the oxide film, relatively free from external disturbances and not obeying the gas laws. Oscillograms from an electrolytic condenser under pressure are shown in Fig. 17.

The results of some measurements by the writer on electrolytic condensers operating in alternating current circuits at very low voltages are shown in Fig. 18. For both aluminum and tantalum the effective capacity decreased rapidly when the applied voltage fell below five millivolts. Both condensers were symmetrical condensers for a-c. operation formed to 60 volts a-c. at 60 cycles, and all measurements were made at 60 cycles.

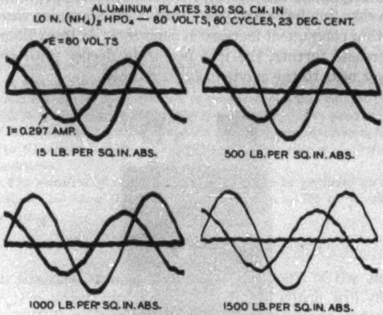

Fig. 17—Aluminum Electrolytic Condenser under Hydrostatic Pressure

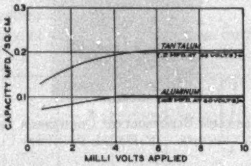

Fig. 18—Electrolytic Condensers with Very Low Applied Voltages on 60 Cycles A-C.

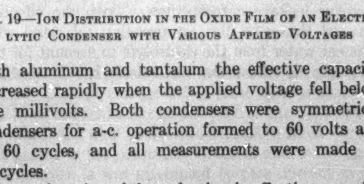

Fig. 19—Ion Distribution in the Oxide Film of an Electrolytic Condenser with Various Applied Voltages

An explanation of the reduction in effective capacity can be made on the basis of diffusion of ions throughout the oxide film under accelerating fields. Referring to Fig. 19, there are shown in an illustrative manner cross-sections of an oxide film under three conditions of impressed voltage. For the case of zero applied voltage very few ions from the electrolyte penetrate the oxide film, and the effective thickness of the film approaches the gross thickness. When low voltages are impressed more ions penetrate the film under the accelerating fields, and the effective thickness decreases with a consequent increase in capacity. As the voltage increases further, the ions penetrate deeper until the layer next to the anode metal is reached.

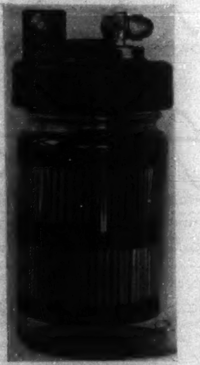

FIG. 20—TANTALUM ELECTROLYTIC CONDENSER FOR BATTERY CHARGING CIRCUITS. (FANSTEEL PRODUCTS CO., INC.)

Any ions penetrating this film constitute leakage current; the film therefore preserves a fairly constant thickness of effective film by natural growth resulting from leakage current. Thus after a certain critical voltage is reached for a given film the effective capacity of the film can change only slightly with variations in voltage.

Summarizing the foregoing, it appears that the normal film in electrolytic condensers is an oxide or hydroxide of the anode metal which is of a greater gross thickness than the effective film, this effective film maintaining itself relatively impermeable to ion penetration by the expedient of natural growth of film wherever leakage currents flow. Both the effective film and the gross film are probably saturated with sufficient water from the electrolyte to account for the extremely high capacities encountered by virtue of the high dielectric constant of water, approximately 80. A dielectric constant approaching this value for the effective film makes possible films of sufficient thickness that the voltage gradients encountered formerly may be materially reduced.

Recent work of the writer has shown that polarization capacity may account for a large part of the measured capacity, this polarization probably occurring in the outer layers of the gross film. A future paper discusses the influence of polarization in electrolytic condensers.

The writer wishes to express here his appreciation of the assistance received from the members of the Electrical Engineering Department of Sheffield Scientific School of Yale University, a large portion of the preparatory work having been done at Dunham Laboratory of Electrical Engineering. Particular appreciation is expressed to Prof. Wesley B. Hall for much constructive criticism, and to former Prof. A. E. Knowlton for valuable assistance in the preparation of this paper.

Power Losses in Electrolytic Condensers

BY F. W. GODSEY, JR.*
Associate, A.I.E.E.

Synopsis.*—Electrolytic condensers on a-c. circuits have higher power losses than would be expected from the leakage currents and electrolyte resistances. Likewise, losses change with the applied voltage, with temperature of the cell, with the frequency of the applied voltage, and with external circuit conditions governing current wave shape in such ways that it is almost impossible to predict results in advance.*

The current wave usually contains large harmonics when a sine wave of voltage is impressed, indicating a non-linear function in the impedance of electrolytic condensers. Increases in voltage, frequency, electrolyte temperature, and concentration of the electrolyte cause increases in the harmonics in the current wave.

Dielectric losses in an oxide film or a gas-oxide film are too low to account for the total losses in electrolytic condensers; and in general the losses in a polarization cell are higher than those found in electrolytic condensers. Polarized cells show some characteristics which are similar to the peculiarities of electrolytic condensers; a number of low-voltage condensers very closely approach the action of polarization cells.

Electrolyte potentials of symmetrical condensers on a-c. circuits are lower than the theoretical values. These discrepancies can be accounted for only by a voltage distribution in the electrolyte. Controlling the potential from outside sources has small influence on power losses except for extreme values of potential.

An equivalent circuit can be drawn for a condenser from the losses, the applied voltage, and the electrolyte potential. On the basis of dielectric theory, the principal portion of the losses is attributed to the voltage drop above the rectifying region. The losses now approach those for a polarization cell.

A film on the anode surfaces saturated with the electrolyte solvent would explain the characteristics as measured, and also make it possible to predict characteristics with some accuracy. Ion penetration of the outer regions of the film and a comparatively continuous film near the anode explain the non-linear characteristics of electrolytic condensers.

The variation of the electrolyte potential can be predicted on the basis of the above theory, and power losses are also more easily predictable.

ELECTROLYTIC condensers consist of electrodes immersed in proper electrolytes with means for obtaining electrical contact to the electrodes and the electrolyte. The action of electrolytic condensers is due to films formed on the surfaces of the anodes. One class of condenser known as the dry type utilizes a hygroscopic, viscous electrolyte which will not flow from between two parallel electrodes separated by a suitable spacer,[1] such condensers have comparatively short electrolyte paths, and consequently much lower electrolyte resistance. They possess the further advantage that it is very simple to roll the electrodes and the electrolyte into a compact cartridge similar to the impregnated paper condensers. One such condenser is now available having 2.5 μf. of capacity per cubic inch of space, with a rated voltage of 450 volts.

Three of the important film theories include the electromotive equilibrium theory, the solid oxide film, and the gas-oxide film theory. The writer's adsorbed liquid theory supplements the older theories.[2] The solid oxide film theory considers that the entire electrical stress is distributed across the oxide film as the dielectric.[3] The gas-oxide theory postulates an inactive film of oxide and hydroxide which serves to support an extremely minute layer of gas carrying the major portion of the electrical stress.[4] The electromotive equilibrium theory states that the oxide film is only supplementary to the principal action of the condenser which is entirely electrochemical in nature.[5] The writer's adsorbed liquid theory[2] more recently advanced proposes that the oxide film is the carrier of an adsorbed volume of liquid, the solvent of the electrolyte, which carries ions the signs of which will vary with their positions with respect to the anode and the applied voltage. This theory takes advantage of the fact that the solvent, in most cases water, has a dielectric constant over 80.

As a source of power loss, the leakage current of the majority of the electrolytic condensers is negligible, Fig. 1. Leakage current will in most cases account for less than one-tenth of one per cent of the total losses. A redissolving film[6] which would dissolve when current was passed in the permeable direction and would again reform when it was attempted to pass current in the

impermeable direction would account for high losses, but this theory is open to many objections.

Resistance of the electrolyte can be controlled by the temperature of the condenser, and by the composition of the electrolyte; the majority of suitable electrolytes have high electrical resistance. However, the power factor of an electrolytic condenser increases with rising voltage, Fig. 2. Increases in temperature should reduce power losses, but measurements show increased losses with increasing temperatures, Fig. 3. The anode construction of Fig. 4 gives rise to a temperature power factor curve such as shown in Fig. 5 due to the long current conduction paths to a large portion of the anode. This defect has been overcome to some extent by special shaping of anodes and venting in suitable places.[7]

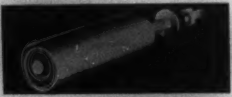

FIG. 4—ANODE CONSTRUCTION OF 8-MICROFARAD ALUMINUM FILTER CONDENSER FOR RADIO USE, 450-VOLT RATING

Typical electrolyte resistances range from 400 ohms to 100 ohms per cm. cube for aluminum condensers, and may go as low as 3 or 4 ohms per cm. cube for low voltage tantalum condensers. The total resistance of the electrolyte of the condenser of Fig. 2 and Fig. 3 is approximately 0.8 ohms, decreasing possibly 50 per cent for the higher temperatures of Fig. 3. The maximum power loss in the electrolyte of this condenser accounts for a power factor slightly under one-half of 1 per cent, much lower than the over-all values which range from 1.25 to 20 per cent. Tantalum in sulfuric acid emphasizes the inadequacy of the resistance of the electrolyte to explain the power losses in electrolytic condensers, Fig. 6; the total resistance of the electrolyte is only a few hundredths of an ohm, and the power factor would be less than one-tenth of one per cent were the losses found in the electrolyte.

When a sine wave of alternating voltage is applied to an electrolytic condenser, large variations in current wave shape are found (Fig. 7); the oscillograms show the current waves 180 deg. out of phase. The wave shapes for aluminum anodes are different in detail from tantalum, but of the same general form, Fig. 8.

Temperature increases result in increases in current and a shift in phase angle toward higher power factors as shown in Fig. 9. These changes are small in so far as the wave shape is concerned until comparatively high temperatures are reached. Changing the concentration of the electrolyte does not seem to alter the effect of temperature changes to any great extent except by a further shift toward an increase in power factor when comparatively high concentrations are reached. (Figs. 10 and 11.)

Increases in the frequency of the voltage applied to the condenser are evident in the current wave shape in the same manner that all influences tending to increase the current loading per unit of area of the anodes become evident, namely by increases in the harmonics and a general if not rapid decrease in phase angle. However, the out-of-phase component of current is as usual almost unchanged as seen in Fig. 12.

In general, the current wave shapes of electrolytic condensers in circuits where sine waves of alternating voltage are impressed may possess a large number of harmonics of varying amplitudes. Any changes in operating conditions which tend to increase current density at the anode surface will increase the amplitudes of the harmonics. The harmonics are usually distributed in such a way that a distinct peak in current is evident aside from the out-of-phase condenser component of current which is plainly evident and changes very little, this peak occurring in phase with the impressed voltage.

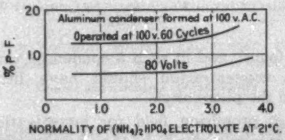

FIG. 11—POWER FACTOR VARIATIONS WITH CHANGES IN ELECTROLYTE NORMALITY IN AN ALUMINUM CONDENSER

Power factors of electrolytic condensers are high for reasons other than leakage and resistance. To ascribe an additional loss to a poor phase angle for the effective dielectric film will account for another part of the total loss. Adhering to three of the original film theories presented, the solid oxide film, the gas-oxide film, and the adsorbed liquid film, the possibilities of the three can be investigated. The solid oxide film theory calls for an extremely thin film of oxide of the anode metal, which may however be shielded to some extent by a gross thickness of film in which there is considerable penetration of the electrolyte. The phase angle of a crystalline film would be much too small to account for the large losses encountered; and the action of an amorphous layer of oxide only a few millimicrons thick is as yet unknown. The gas-oxide theory is open to the same objections from the standpoint of power losses, a thin gas film merely being substituted for the thin oxide film. The adsorbed liquid theory offers more possibilities since polar rotation is undoubtedly present to account for the high dielectric constants, yet it is doubtful that the losses could ever approach the losses found; and in such a condenser variations in electrolyte concentration should have little or no effect upon the phase angle.

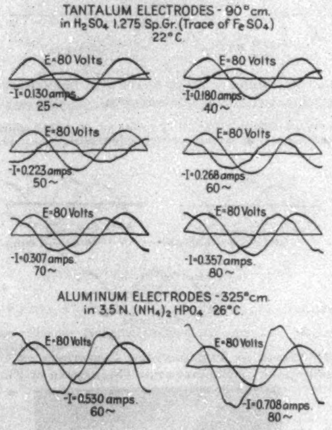

FIG. 12—INFLUENCE OF FREQUENCY ON CURRENT WAVE SHAPE

The most promising field for investigation of the power losses now seems to be the electromotive equilibrium theory. As mentioned above, the electromotive equilibrium theory considered alone is insufficient to explain all the action occurring in electrolytic condensers, but the extent to which polarization capacity enters the question has been investigated in some detail.

An electrolytic cell capable of polarization can be subjected to a flow of current and then discharged through a resistance, acting in some respects as a condenser which has been charged and which has a certain capacity; this is known as the polarization capacity of the cell. Its place is the point of contact between the electrode and the electrolyte, and is quite distinct from the case of a non-conducting layer, for instance an oxide layer as on an aluminum condenser. Polarization capacities have been found to be dependent upon the frequency of the impressed voltage and the magnitude of the voltage or current intensity; and the phase displacement varies from 0 deg. to 90 deg. leading. There are in general three characteristic groups into which electrolytic cells may be divided.

The capacity may be independent of the frequency of the impressed voltage, and the phase displacement is zero or at least very small. The capacity can be considered as the result of an electric double layer as it must exist according to Helmholtz at point of contact of electrode and electrolyte, or perhaps produced by a condensation on the surface of the electrode of the dissolved metal salt according to Warburg. The double layer capacity is especially effective in small concentrations of ions, which practically eliminates it from consideration in electrolytic condensers of the aluminum and tantalum anode type for high current densities and voltages over a few volts.

The polarization may be due to the change in concentration and the diffusion of the dissolved salt. Warburg, M. Wein, and Neumann have shown that the capacity, in case the diffusion predominates, is inversely proportional to the square root of the frequency, with a phase angle of 45 deg. leading. The double layer exists in these cases also, but it becomes entirely insignificant compared to the influence of diffusion if the concentration of ions of the dissolved salt is not too small.

In the case of a salt so little dissociated and of such a concentration that a polarization on account of the change in concentration of the salt under weak currents is imperceptible, nevertheless a polarization can occur, if the speed of dissociation of the non-dissociated part of the salt does not ensue quickly enough compared to the current change to prevent a change in ionic concentration. In this case the capacity is inversely proportional to the frequency, and the phase displacement is 90 deg. This case was found experimentally by M. Wein on palladium heavily charged with hydrogen—and by Kruger with mercury electrodes in solutions of complex mercury salts. This is another case that need not be confused with the action in the ordinary electrolytic condensers.

It therefore appears that the only case of polarization capacity which must be considered is the case of concentration or diffusion capacity. Warburg[8] has developed the theory of concentration cells when a sine wave of alternating current is forced through the cell. Selecting a symmetrical cell with parallel plate electrodes

$$E = \frac{\alpha}{K\omega} \sin\left[\,\omega - \frac{\pi}{2} + \psi\,\right]$$

where K is the polarization capacity. The value of the constant ψ is $\frac{\pi}{4}$ for this case, and

$$K = \frac{c_0\sqrt{kqe^2y}}{2RT\sqrt{\omega f}}$$

In the above equation R is the gas constant, f is the number of ions given by one molecule of the salt, y the total valency of ions from one molecule, and T is the absolute temperature.

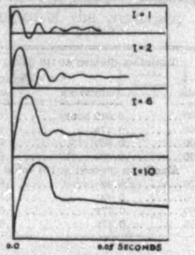

Fig. 13—Degeneration of Oscillatory Charge of Polarization Cell Due to Increase in Current Density

Thus, the current is found to lead the voltage by 45 deg. when a sine wave of voltage is impressed on a concentration cell for low values of current density. The capacity is also observed to be inversely proportional to the square root of the frequency.

When the current density is high the above relation is no longer true, and harmonics are introduced into the current wave when a sine wave of voltage is impressed. However, it is very interesting to note that the effective capacity will not change greatly, and the phase angle of 45 deg. is particularly interesting from the standpoint of power losses in electrolytic condensers.

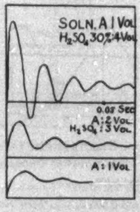

Fig. 14—Degeneration of Oscillatory Charge of Polarization Cell Due to Increased Ion Concentration

Kruger[9] developed equations for the charge of polarized cells in inductive circuits, and obtained experimentally the necessary results to confirm them. Very low voltages were applied to the cells to avoid gas polarization, and it was found that increases in current density would change a charge from an oscillatory charge to an aperiodic charge, Fig. 13. Likewise, increases in the ion concentration of the solution show the same effect, Fig. 14; and one very interesting development is the fact that an oscillatory circuit can be converted very easily to an aperiodic circuit by increasing the inductance in the circuit. It is also observed as a definite characteristic of most electrolytic cells that only a definite number of oscillations occur before the charge degenerates into an aperiodic form which may tail-out indefinitely.

The behavior of an electrolytic condenser made up with nickel anodes in a caustic solution for use in low-voltage filters was very similar to the action found by Kruger for concentration cells. The charging characteristics were strongly suggestive of a condenser in which concentration capacity plays a large part, Fig. 15: the discharge characteristics in inductive circuits also indicate the predominance of concentration capacity with very high initial concentration in the electrolyte. A low-voltage electrolytic condenser of the semi-dry type intended for the same low-voltage filter use showed better condenser characteristics, Fig. 16. The charging characteristics of the semi-dry condenser were found to approach those of a perfect condenser, although the decrease in charging current

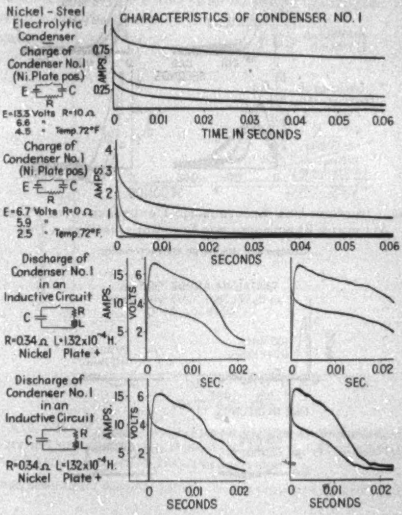

Fig. 15—Low-Voltage Filter Condenser with Large Amount of Concentration Capacity

Charge and discharge characteristics

with time was not rapid enough to satisfy a logarithmic function.

When a high-resistance film is present on the surface of an electrode immersed in an electrolyte, somewhat different results may be expected than from the case of diffusion capacity alone. However, diffusion capacity undoubtedly exists at the point of contact of the film and the electrolyte.

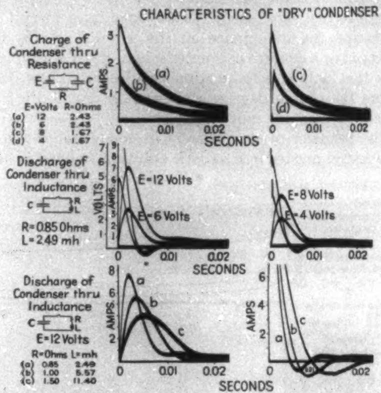

Fig. 16—Semi-Dry Electrolytic Condenser with Pasted Aluminum Electrodes for Low-Voltage Filter Use

Charge and discharge characteristics

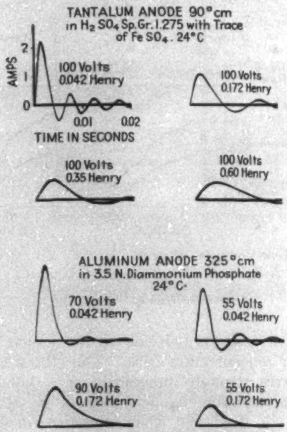

Fig. 17—Oscillatory Discharge of Electrolytic Condensers in Induction Circuits of Very Low Resistance

Ordinary aluminum and tantalum condensers were discharged through inductive circuits and oscillograms of current were obtained, Fig. 17, with strong indications of the presence of diffusion capacity. Tantalum showed the characteristic increase in attenuation of the oscillatory component with increase in inductance, and also was noteworthy in that the period of the oscillatory component became shorter as the cell discharged and the concentration decreased. Aluminum indicated an even greater diffusion capacity than tantalum, and the decrease in attenuation is strikingly evident as the initial concentration is decreased for the same circuit conditions by lowering the initial voltage. Increasing the inductance of the discharge circuit for the aluminum condenser caused a rapid approach to the aperiodic discharge predicted by Kruger[9] for concentration cells.

TABLE I

Volts	Inductance	Capacity μf. per sq. cm.
Tantalum (formed at 110 volts)		
100	0.042 henry	0.201
100	0.172	0.190
100	0.350	0.170
100	0.600	0.161
Aluminum (formed at 110 volts)		
70	0.42	0.085
55	0.42	0.091
90	0.172	0.093
55	0.172	0.087

The effects of diffusion or concentration capacity in ordinary electrolytic condensers are somewhat similar to the effects predicted for simple concentration cells; but there is the fundamental difference in that in most electrolytic condensers the diffusion capacity is in series with a more or less effective dielectric layer.

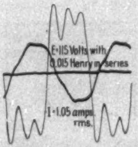

Fig. 18—Aluminum Electrolytic Condenser Formed at 120 Volts in 1.75 N. Diammonium Phosphate in Series with Inductance of 0.015 Henry

Area of aluminum electrodes 350 sq. cm. each, temperature 23 deg. cent., total applied voltage 115-sine wave 60-cycle.

The following capacities calculated from the oscillograms of Fig. 17 by integrating over the first quarter cycle of the discharge to find the coulombs of electricity stored in the condenser for a given voltage, show a decrease in effective capacity for decreasing frequency, Table I.

These variations in effective capacity have been noticed in electrolytic condensers only in freely oscillating circuits and exist to a negligible extent in circuits where alternating voltages are impressed from a source of power supply. Condensers with non-linear current voltage characteristics are difficult to handle as simple capacities without introducing errors.

Harmonics in the current wave can be emphasized in a-c. circuits by placing inductance in series with the condenser, Fig. 18.

In a symmetrical electrolytic condenser on a-c. circuits, in order to prevent heavy leakage currents, it is necessary that the aluminum or tantalum electrodes always have a positive potential with respect to the electrolyte of the condenser. Assuming an equal voltage division between electrodes, the maximum alternating voltage applied to one electrode is equal to half of the total applied voltage. The maximum instantaneous voltage is therefore equal to 0.707 by the total applied voltage, and the d-c. potential of the electrolyte which must be negative with respect to the electrodes at all times is therefore equal to 0.707 by the a-c. voltage on the condenser. In order to insure a minimum of leakage, it is possible to raise the potential of the electrodes with respect to the electrolyte by means of a separate source of direct current, Fig. 19. Referring to Fig. 2, the power factor is improved greatly by operating the condenser on an a-c. voltage well below the voltage of formation; by maintaining the voltage of formation higher than the operating voltage by means of some external source of direct current it should be possible to greatly improve the power factor, providing that other effects do not overweigh the advantages gained. However, when the voltage of the electrolyte was controlled from an external source, the expected results were not obtained, very little if any improvement in power factor being noted. (Figs. 20 and 21.)

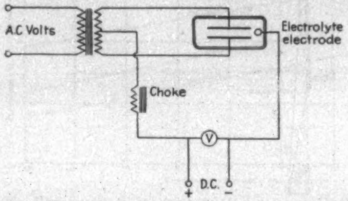

Fig. 19—Circuit for Applying and Measuring Electrolyte Potential in Electrolytic Condensers on A-C. Circuit

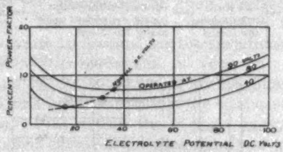

Fig. 20—Power Factor Control by Means of Control of Electrolyte Potential of Electrolytic Condenser

Since there was no improvement in power factor when the electrolyte of a symmetrical condenser was maintained at the proper potential with respect to the electrodes by auxiliary means, the actual potential of the electrolyte was measured with an electro-static voltmeter connected to the midpoint of the transformer supplying the condenser and to the electrolyte. The potentials found for aluminum and for tantalum electrolytic condensers were 50 to 75 per cent of the expected values, Fig. 22. These departures from the theoretical values on the basis of complete rectifier action at the film and a dielectric capacity type of condenser are much too large to admit of experimental error, and furthermore are very consistent in their values.

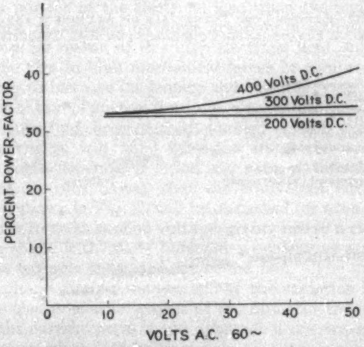

Fig. 21—Variations of Power Factor of 8-Microfarad Filter Condenser with Amplitude of the A-C. Component for Various Values of D-C. Polarization

High power factor due principally to the long electrolyte conduction paths

It was thought at first that these low values might be due to a pulsating electrolyte potential which would reach a maximum value of the theoretical voltage twice every cycle, but subsequent oscillograms of the variation in electrolyte potential disclosed a ripple in the d-c. voltage of approximately one-quarter of one per cent or less, Fig. 23. This is further proof that losses in electrolytic condensers on a-c. circuits should not be ascribed to leakage current when operated at normal voltages.

The maximum value of alternating voltage applied to the rectifying film on the electrodes of electrolytic condensers is therefore 50 to 75 per cent of the theoretical value.

The phase angle of the part of the electrolytic condenser across which this voltage appears is an unknown quantity; but if it is assumed that this effective film is any one of the three mentioned above, a solid dielectric, a gas filled solid, or a liquid filled solid, the phase angle is extremely close to 90 deg. leading.

On the assumption that the power loss in the effective film is negligible, it is possible to locate the voltage vector of the effective film with respect to the current and voltage vectors for the entire condenser, Fig. 24. The condenser current I_c is shown leading the total applied voltage by the phase angle α, and the effective film voltage E_{eff} is approximately in quadrature with the condenser current. In order to complete the voltage triangle, the vector E_{e1} must be added with a phase angle of β with respect to the condenser current. This vector E_{e1} is of interest now, since the power losses are practically all accounted for by its phase angle; it is the voltage drop which appears in the electrolyte of the condenser, and it has just been shown that the voltage drop in the electrolyte is much too small as calculated to account for the magnitude of this vector on the basis of a resistance drop, furthermore the phase angle shows that it is not a pure resistance.

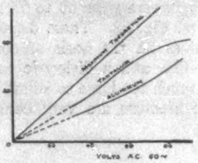

FIG. 22—ELECTROLYTE POTENTIALS OF ALUMINUM AND TANTALUM ELECTROLYTIC CONDENSERS ON A-C. CIRCUITS

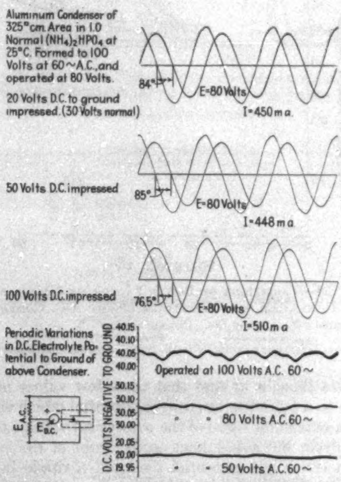

FIG. 23—EFFECT OF WAVE SHAPE ON IMPRESSED ELECTROLYTE POTENTIAL, AND THE NORMAL FLUCTUATIONS IN ELECTROLYTE POTENTIAL

It becomes very quickly apparent upon consideration of the properties of this residual voltage vector after all of the measurable quantities are accounted for, that the electromotive equilibrium theory is justified to some degree. The phenomenon of polarization capacity will account for the leading phase angle of the vector E_{e1}, and when a larger portion of the loss is assigned to the voltage appearing across the effective film, the phase angle of the electrolyte voltage vector increases. Thus, it appears that in the great majority of electrolytic condensers of the formed film type there are two distinct kinds of capacity present, dielectric capacity and polarization capacity.

FIG. 25—SCHEMATIC DRAWING OF CROSS-SECTION OF FILM ON ELECTROLYTIC CONDENSER ANODE

Showing regions of high and low ionic penetration and the equivalent circuit diagram

Selecting a typical example of an aluminum condenser, with a total impressed voltage of 80 volts at 60 cycles, the power factor was found to be 9 per cent. The d-c. potential of the electrolyte was measured at 32 volts, leaving a distribution of 44.8 volts on both electrodes of the symmetrical condenser in series. The remainder of the out-of-phase voltage 34.8 volts, appears as a voltage drop in the electrolyte. Added to this quadrature drop is the in-phase drop of 7.2 volts, giving a total drop in the electrolyte of 36 volts at 20 per cent power factor, or a phase angle of approximately 78 deg. leading. The resistance of the electrolyte will account for less than one volt drop, and that in phase with the current; apparently polarization is occurring in the gross film covering the effective film, or very near to the gross film.

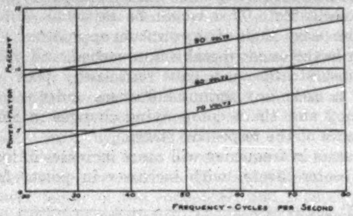

Fig. 26—Effect of Variations in Frequency Upon the Power Factor of Electrolytic Condensers

Aluminum plates 350 sq. cm. in diammonium phosphate 1.0 N. at 23 deg. cent. (formed at 100 volts)

However, polarization capacity of the kind found in this type of electrolytic condenser was found to have a phase angle of 45 deg. leading, which does not agree with the 78 deg. for the above case. Obviously, there are modifying factors and it will appear that polarization capacity as such must be handled differently than from the standpoint of clean electrodes in an electrolyte. The writer has advanced a theory of film penetration to account for the variations in capacity of electrolytic condensers at very low voltages.[2] A diagrammatic cross-section of such a film is shown in Fig. 25, and below it is shown the equivalent circuit. In the equivalent circuit, the in-phase components of the equivalent circuit are shaded lightly or heavily, to indicate low conductivity or high conductivity of the film at that point as the case may be.

Calculations from the measured capacities of such anodes show that the gross film as measured by optical methods may reach thicknesses as great as fifty times that necessary for the requisite capacity. Thus, it is necessary that the film be conducting through at least a part of its thickness, and it can best be described as a semi-permeable membrane which increases in density as the anode is approached.

In such a film structure, the penetration of the film by the electrolyte will be retarded in the case of cations by reason of the direction of the electric field, and in the case of anions the field will accelerate them to even further penetration than under the case of normal diffusion. By way of explanation, the terminology used for the anion and the cation assigns to that ion which is attracted to the cathode the name cation, and vice versa, there being some ambiguity in the terms as used by physicists and electrochemists.

Thus referring again to Fig. 25, a film of insulating material of a thickness comparable with the wave-length of visible light, varying in composition from an extremely dense layer against an anode to a relatively porous outer surface and presumably saturated with water, acquires a space charge which varies in density with the location in the film. The distribution of the electrical field through the film will depend upon the configuration of the space charge and movements in the film, assuming that the film material itself is a relatively good insulator. Thus, the potential gradient will increase as the anode is approached, placing a larger portion of the electrical load upon the region of the film unoccupied by large numbers of anions; and likewise by reason of this high electrical field, subjecting the film to high mechanical forces in compression, tending to increase its density and continuity.

The action of such a film in an electrolytic condenser with pulsating direct current applied is such that the space charge will vary with the impressed voltage, with some dependence upon the rate of diffusion of anions, in such a way that the equivalent electrical circuit shown in Fig. 25 will be disturbed for even small changes in total applied voltage, giving rise of a current wave shape with many harmonics evident as a result of the variable characteristic of the film. The smaller the voltage change, the less will be the variation in the space charge characteristics of the film and the nearer will the current wave shape approach a sine wave for a sine wave of applied voltage.

The region of the film nearest to the anode was described as being relatively free of ions; whether or not it is saturated with the solvent of the electrolyte is open to question, but it is more likely that it is saturated than not since the dielectric constants of the aluminum compounds are relatively low compared to water, and the volt-ampere loading of this region would be excessive in the case of low dielectric constants. This portion of the film is shown in the equivalent diagram as pure capacity with little or no resistance loss, and it is believed that across this region the rectifying action of electrolytic rectifiers occurs. The

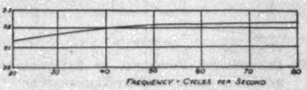

Fig. 27—Effect of Frequency Upon Electrolyte Potential of Symmetrical Electrolytic Condenser

Aluminum

boundary can be fixed definitely on the side adjacent to the anode metal, but on the other side of this rectifying region of low dielectric loss and high electrical resistance, the boundary cannot be fixed so definitely. It moves about with the applied voltage, the thickness of the formed film, the mobilites of the anions, and the temperature of the film and electrolyte. Thus, the leakage current and breakdown voltage of a particular film are dependent upon the above mentioned variables. No definite plane of demarcation between the rectifying region and the adjacent region saturated with ions can be located, the one shading gradually into the other. A definition of the boundary of this rectifying region can be stated as the point at which the maximum voltage drop from the anode is equal to the electrolyte potential when the film is made half of a symmetrical electrolytic condenser in an a-c. circuit.

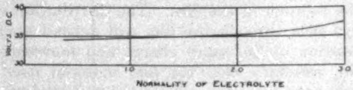

FIG. 28—EFFECT OF ELECTROLYTE CONCENTRATION UPON ELECTROLYTE POTENTIAL OF SYMMETRICAL CONDENSER

Aluminum

The entire film is then seen to form a dielectric sheet similar to the stratified dielectric of Maxwell showing absorption as do all stratified films; and possessing the further interesting feature that the leakage of any one strata is controlled by many factors, and will change periodically with an applied periodic voltage variation, giving rise to a dielectric sheet with a non-linear voltage-current characteristic.

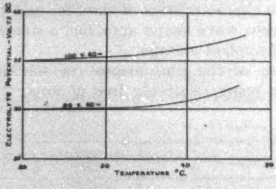

FIG. 29—ELECTROLYTE POTENTIAL OF ELECTROLYTIC CONDENSER AS INFLUENCED BY TEMPERATURE

Aluminum

For the current flow in the resistance paths, the ions in the film constitute the space charge in the film and must also supply the electrical charge to take care of the excess voltage imposed on the rectifying film by reason of the resistance paths. Thus, the ions in the film fulfil two requirements, the one providing electrical conductivity through regions of the film and the other providing an electrical charge of real thickness to supplement the dielectric strain in the parallel strata. The thickness of the ionic space charge influences the characteristics of the condenser, as well as does the mobility of the ions in the film. The increase in effective capacity of the condensers in the above described freely oscillating circuit with increases in natural frequency of the circuit, Table I, can then be attributed to the predominance of the leakage resistance paths over the space charge effect in the cases cited. However, this is the only case where such action has been noted by the writer, the effect of variations in frequency upon effective capacity usually being negligible. This would be expected ordinarily since the phase angle of any stratum approaches 90 deg. leading as the anode metal is approached, and only the outermost strata must have sufficiently poor phase angles to exert any serious influences under increased frequency and the accompanying changes in relative impedance of the respective strata.

Increases in frequency will cause increases in loading of the outer strata, with increases in power factor. The effect of frequency upon the power factor of an aluminum electrolytic condenser is shown in Fig. 26, and the variation in d-c. potential of the electrolyte for the same condenser is shown in Fig. 27.

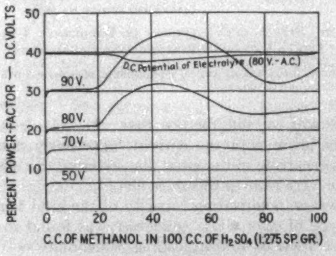

FIG. 30—ELECTROLYTIC CONDENSER POWER FACTORS AS CONTROLLED BY SOLVENT OF THE ELECTROLYTE

Tantalum condenser

Increasing the concentration of the electrolyte should increase the space charge density in the film, with a resultant increase in d-c. potential of the electrolyte, Fig. 28. The condenser illustrated in Fig. 28 is the same condenser as in Fig. 11.

Variations in impressed voltage have a similar effect to both frequency changes and increased concentration for high voltages; and the results are shown in Figs. 2, 6, and 22. Increases in the space charge density are general for increases in voltage, with particularly high increases in the outer strata. Temperature rises produce a similar effect to voltage rises through increased mobilites of anions, Fig. 29.

The temperature drop through the film can be calculated from the known losses and the assumption that the transfer of heat from the film to the electrolyte follows the general rules of heat transfer between liquid and solid surfaces in contact, a value of approximately 7.3 g-cal. per sq. cm. per hour per deg. cent., being acceptable for the case of electrolytic condensers. For the condenser of Fig. 2, with a total area of both electrodes of 700 sq. cm. and a current flow of 400 milliamperes at 100 volts, the power factor is 17 per cent. The loss per hour is 6.8 watt-hr. or 5,860 g-cal. per hour, with a temperature difference between the film and the electrolyte of approximately 1.15 deg. cent.

An attempt was made to change the capacity of a tantalum electrolytic condenser by changing the nature of the solvent for the electrolyte. Methyl alcohol was added to sulfuric acid electrolyte, with some expectation that penetration of the film by the alcohol might occur with a consequent loss in capacity due to the lower dielectric constant of methyl alcohol as compared with water, approximately 30 to 80. Capacity variations were negligible, and the small errors in observation were as large as the observed variations. However, some very curious effects were noticed upon the power factor of the condenser, and a small effect upon the d-c. potential of the electrolyte for the higher operating voltages. The peculiar humps in the curves of Fig. 30 are attributed to the increased loading of the outer strata of the film due to penetration by the alcohol, thereby increasing the voltage drop in the outer strata and thus raising the power factor. The curve of d-c. potential of the electrolyte against alcohol content indicates this action also. Work on electrolyte condensers was discontinued before any further investigations could be made along similar lines.

The author wishes to express his appreciation to Professor Wesley B. Hall of Sheffield Scientific School of Yale University and to Mr. A. E. Knowlton, formerly of Yale for their valuable assistance rendered in the preparation of the material for this paper both while at Yale and subsequently.

Discussion

FILM CHARACTERISTICS OF ELECTROLYTIC CONDENSERS

(Godsey)

POWER LOSSES IN ELECTROLYTIC CONDENSERS

(Godsey)

H. H. Race: Figs. 25 and 26 of Mr. Godsey's paper interested me particularly because of some recent work in our laboratory which may help to explain power factor—frequency characteristics of electrolytic capacitors even though it was undertaken for an entirely different purpose. In studying the causes of dielectric loss in insulating materials we have made artificial imperfect dielectrics by sealing conducting liquids in fused quartz tubes. We have found that the measured effective capacitance and dielectric loss as functions of frequency of such a composite dielectric can be completely explained in terms of the equivalent circuit shown in Fig. 1 which may be reduced to the simpler circuit shown in Fig. 2.*

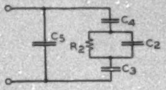

Fig. 1—Equivalent Circuit of Fused Quartz Tubes Containing a Conducting Fluid

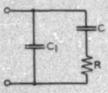

Fig. 2—Simpler-Circuit Which Can be Made Equivalent to Fig. 1 by the Use of Definite Algebraic Relations Between Coefficients

If a dielectric can be represented by the equivalent circuit of Fig. 2 in which the coefficients are assumed to be independent of frequency, then the general form of the effective capacitance and loss curves will be as shown in Fig. 3.

If the coefficients of capacitance and resistance in Mr. Godsey's Fig. 25 can be assumed to be independent of frequency then this complicated combination of series and parallel arrangements of resistance and capacitance can be reduced to an equivalent circuit similar to Fig. 2 above and the changes in effective capacitance and loss with frequency in an electrolytic capacitor should follow Fig. 3. Thus Fig. 26 may be only a special case of this more general form.

Probably the coefficients in Fig. 26 cannot be assumed to be independent of frequency since the ionic concentration at a given point in the oxide film will change with time. Nevertheless, I feel that a study of the dielectric properties of electrolytic capacitors over wide ranges of frequency and temperature should add considerably to existing knowledge of the mechanism involved.

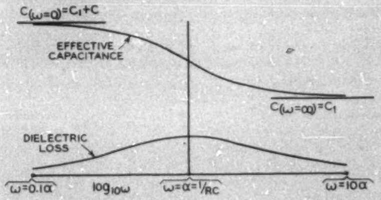

Fig. 3—Variations with Frequency of Effective Capacitance and Dielectric Loss for the Equivalent Circuit Shown in Fig. 2 (Plotted for Case Where $C = C_1$)

J. Slepian: The principal obstacle to the use of electrolytic condensers in the power field has been the high power factor usually obtained in such cells. An attempt to locate and explain the losses occurring in these cells, such as Mr. Godsey has made in this paper, is therefore extremely praiseworthy.

---

*The results of this study will be published in the near future.

In work which I carried on over a period of years some twelve years ago, I quickly found that the properties of aluminum cells were extremely complicated and that such cells frequently behave in most unexpected ways. For example, it was generally believed that the halogens were extremely deleterious. I found that the addition of a fractional per cent by weight of a soluble fluoride had an extremely beneficial effect upon the power factor, reducing the losses generally many fold. With the addition of such traces of fluoride I was able to make cells with power factors under 2 per cent.

However, I was never able to make cells with such low power factors which would stay efficient indefinitely. In all cases there was a gradual rise in power factor with continuous operation over a period of years. Starting at 2 per cent the power factor would become 5 or 6 per cent in the course of a year and continue to rise slowly for years afterwards. This was with a superposed d-c. excitation upon the cells. Without the superposed d-c. excitation the rise in power factor was very much more rapid. Investigation showed that apparently changes in the electrolyte played a part in the rise in power factor since, if the plates of an old cell were placed in fresh electrolyte the power factor returned to a low value, although not quite as low as in the original cell. The power factor rose much more rapidly, however, with time in the new electrolyte than in the old, indicating that there had also been a change in the electrode. The change in the electrolyte I assumed to have been the formation of colloidal aluminum hydroxide and I ask Mr. Godsey if he can suggest any reason why the presence of such substance should effect the losses in the cell.

In general I found that in operation on alternating current some of the generalizations made from d-c. studies were not applicable. For example, on direct current the capacity of an aluminum cell seems to be independent of the nature of the electrolyte and to vary inversely with the d-c. voltage, but on alternating current the capacity was different in different electrolytes and varies with the time. Generally also, the capacity was lowest in those cases where the power factor was low. This may seem to be inconsistent with the picture of Fig. 25 which Mr. Godsey has drawn explaining the losses and it would be interesting to have him comment upon that point.

F. W. Godsey, Jr.: The study of artificial imperfect dielectrics referred to by Mr. Race is interesting from the point of view of electrolytic condensers in that the action in a composite dielectric such as Mr. Race describes would closely approach the action in an electrolytic condenser under certain conditions.

However, the circuit of Fig. 25 is only very roughly equivalent and the coefficient of capacitance and resistance can under no circumstances be assumed to be independent of frequency. This is due to the fact that the conducting particles and ions in the outer layers of the film not only constitute leakage resistance paths, but also constitute a considerable portion of the electrical charge of the inner layers of the film. Thus, the capacitance and resistance coefficient are not only variable for different frequencies, but vary through wide limits for different current densities and applied potentials. It is the author's conclusion that it is a hopeless task to attempt to set up a simple equivalent circuit for an electrolytic condenser.

As Mr. Race suggests, it would add considerably to existing knowledge of electrolytic condensers if a study of the dielectric properties were made over wide ranges of frequency and temperature, provided that sufficient precautions were taken to overcome the inherent difficulties due to electrolyte resistance and cell constants.

Mr. Slepian's comments in connection with the addition of halogens to the electrolyte of electrolytic condensers are very interesting. Since most of the previous work on electrolytic condensers was done on direct current, it was soon found that the addition of halogens greatly increased leakage current for a small amount of the halogen ion. However, as I have shown, the leakage current in electrolytic condensers is in general a negligible factor in computing power losses.

Referring to Fig. 25, it will be seen that the addition of any ion to the electrolyte which will serve to penetrate the outer film layers will reduce the value of leakage resistance in the outer layers.

By a proper control of the leakage resistance of these outer film layers, it is possible to either increase the power factor or to reduce the power factor of the condenser. Theoretically, the power factors encountered will be lower when the resistance is zero and when the resistance is infinite. By the addition of halogens, this resistance can be controlled to some extent and it would appear from Fig. 25, that with increased conductivity of the outer film layers, there should also appear an increase in effective capacitance.

The observation that the capacity in alternating current circuits was lowest in cases where the power factor was low can very probably be assigned to the case of newly formed condensers upon which the oxide films are relatively thin and continuous in the outer layers so that there is less penetration of the outer layers by ions. Upon aging, the film grows in thickness and the continuity of the outer layers is in all probability so broken up that ion penetration is much more readily effected and the leakage currents in the outer layers are therefore excessive. It is apparent from an inspection of Fig. 25 that if the leakage resistance in the outer layers is high, the effective capacity will be low.

Mr. Slepian's suggestion that the formation of colloidal aluminun hydroxide in the electrolyte accounts for a large part of the rise in power factor with time of the electrolytic condensers is I believe, substantiated by the references to the importance of the condition of the outer film layers made in the papers under discussion. The placing of an anode with a formed film upon it in an electrolyte in which there is colloidal aluminum hydroxide would result, upon the passage of current, in the collection of this colloidal hydroxide upon the plate. Since the thickness of the oxide film upon the anode is only about one micron for a 300-volt film, a very small deposit of the colloidal hydroxide would very effectively increase the thickness of the outer film layers and would in all probability increase the series resistance of the outer film layers with an attendant increase in power loss. (Two additional papers on electrolytic condensers were presented at the Sixty-First General Meeting of the Electrochemical Society in Baltimore on April 23, 1932. These papers have some bearing upon the comments of Mr. Race and Mr. Slepian, and are identified as preprint 61-27 and preprint 61-28, pages 331 to 357 inclusive.)

Electrical Precipitation

Some Fundamental Theory and Experiments

BY A. W. SIMON*
Non-member
and
L. C. KRON*
Non-member

WHILE numerous articles have been published on electrical precipitation (the Cottrell process), they have been concerned largely with the engineering features of Cottrell treaters or the special features of the application of the process to particular industries. The fundamental theory of the process or the quantitative laws underlying it, on the other hand, have received but scant attention. From the theoretical side we have but two papers which treat the subject with any degree of thoroughness: one, based on the kinetic theory but limited to tube treaters, by Deutsch,[1] and the other, based on the law of mass action, by one of the present authors.[2] From the quantitative experimental side also but little has come to light; we need mention only that in a paper by Schmidt[3] it is set forth that the precipitation efficiency (percentage removal) is an exponential function of the gas volume treated (although it is not stated what kind of an exponential) and also of the "length of discharge electrode;" while in a paper by Horne[4] the relation between precipitation efficiency (percentage removal) and secondary voltage is exhibited in the form of a curve; further that in another paper by Deutsch it is stated that Horne and Anderson have arrived at an empirical formula, connecting the precipitation efficiency η with the length of pass L and the velocity V of the gas, of the form:

$$\eta = 1 - K^{L/V}$$

and, finally, that Anderson[6] gives the equivalent formula:

$$1 - \eta = K^{t}$$

where t is the time the gas remains in the precipitator.

As a matter of fact, outside of the few points just mentioned, *quantitatively* very little is generally available regarding the fundamental principles involved in electrical precipitation; and many operators today are still entirely in darkness regarding the effect of such fundamental factors as voltage, current, velocity, size of discharge electrode, etc., on the percentage removal, *i. e.*, the "precipitation efficiency".[7] In the present work a number of these relations are, we believe, for the first time, clarified and exhibited.

I. QUANTITATIVE THEORY OF THE COTTRELL PROCESS

From the theoretical point of view it is logical to infer that the Cottrell process can be considered as a reaction between the dust particles on the one hand and the electrically charged gas particles (gas ions) on the other. Such a reaction would presumably follow the law of mass action familiar in chemistry, since after all the chance of a dust particle being precipitated depends on its change of encountering an ion, and therefore should be proportional to the number of ions present, whereas the actual number of dust particles encountering ions should also be proportional to the number of dust particles present. On this basis, if we denote by dq/dt the rate of removal of the dust particles, we have:

$$-\,dq/dt = kqi \qquad (1)$$

where q is the concentration of dust particles at any instant, i is the concentration of the ions, and k a constant, which depends, however, on the particular gas and fume treated.

Integrating this equation directly we have:

$$q/q_o = e^{-kit} \qquad (2)$$

where q_o represents the original concentration and t the treatment time.

This equation can be interpreted in two ways; either statically or dynamically. The static case would correspond to the experiment where the whole volume of the precipitator is filled with a quiescent gas containing suspended material of concentration q_o and the precipitation process is continued for a length of time t, at the end of which period q is the concentration remaining in suspension; the dynamic case, on the other hand, is where the dust-laden gas is flowing through the precipitator, in which case q_o is the entering and q the emergent concentration, and t the time the gas remains in the precipitator.

The left member of (2) is obviously the fractional part of the entering concentration passing through *unprecipitated*, *i. e.*, emerging from the precipitator, whereas in many cases the fractional part *precipitated* is of interest. If we denote this (fractional) part by η, we have that the left member of (2) is equal to $(1 - \eta)$, whence we can rewrite (2) as:

$$\eta = 1 - e^{-kit} \qquad (3)$$

In a particular case we may assume i to be constant, in which case we can put ki identically equal to a new constant α, whence we have as a final result:

$$\eta = 1 - e^{-\alpha t} \qquad (4)$$

Equation (4) expresses two fundamental laws of electrical precipitation, which we shall now consider in detail.

First, from the definition of η, it follows: *The fractional part of the incoming concentration precipitated is independent of this concentration.* This really justifies the use of the quantity η, that is to say, establishes the

---

1. For references see end of paper.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

"precipitation efficiency" (percentage removal) as a uniquely determinable quantity (independent of the incoming concentration).

If interest centers not so much on the amount of material precipitated, as on the *cleanliness* of the emerging gas, it is the quantity $(1 - \eta)$, which we will denote by ξ, which is of importance. In this case we can rewrite (**4**) as

$$\xi = e^{-\alpha t} \tag{5}$$

A second fundamental law which follows directly from eq. (**4**) is that *the fractional part of the incoming concentration precipitated depends on the length of time the gas remains in the precipitator.*

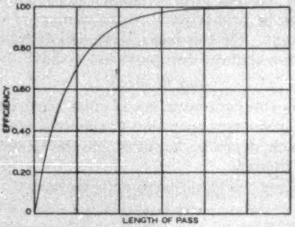

FIG. 1—THEORETICAL PRECIPITATION EFFICIENCY (PERCENTAGE REMOVAL) OF A COTTRELL PRECIPITATOR AS A FUNCTION OF THE LENGTH OF THE PRECIPITATOR

From this law we can deduce directly also how the precipitation efficiency varies with the gas volume V (treated per minute) and the distance D traversed by the gas in the precipitator, *i. e.*, the "length of pass." Obviously, if A represents the effective cross-section of the treater, these quantities are related to each other, and also to the velocity v of the gas in the precipitator by the equation:

$$t = D/v = DA/V \tag{6}$$

whence we can rewrite (**4**) in the several forms:

$$\eta = 1 - e^{-\alpha D/v} \tag{7}$$

$$\eta = 1 - e^{-\alpha AD/V} \tag{8}$$

$$\eta = 1 - e^{-KD/V} \tag{9}$$

where K is a constant of the precipitator depending, however, on the particular gas and fume treated and on treater conditions (temperature, etc.), but, of course, not on D and V. Eq. (**9**) expresses some important facts regarding Cottrell treaters now to be considered in greater detail.

In order to exhibit the relations expressed by eq. (**9**) more clearly, the curve giving the precipitation efficiency as a function of the effective length of the treater is reproduced in Fig. 1; and as a function of the *volume treated per minute* (or its equivalent the velocity of the gas in the treater) in Fig. 2. Anticipating somewhat, it might be stated that most of the quantitative laws involved in electrical precipitation satisfy or approximate either one or the other of these curves, so that they may be regarded as the two fundamental types of characteristic curves of the Cottrell process.

Without, for the moment, going into the mathematical relations, it will be seen from Fig. 1 that the cleaner the gas becomes, that is to say, the more dust is precipitated, the more difficult it becomes to precipitate the remaining dust or to make the gas cleaner, a fact which in practise is found pretty much universally true. In fact the curve of Fig. 1 really expresses a law which holds generally for gas cleaning; for the assumptions made in deducing eq. (**9**) for Cottrell cleaning hold also *mutatis mutandis* for other types of cleaner. To be specific, it will be noted that the foregoing theory is based on the chance of an encounter between a gas ion and a dust particle; however, it might equally well be, in the case of a wet washer, the chance of a water droplet encountering a dust particle, or in the case of a bag filter, the chance of a fiber ensnaring a dust particle. Therefore, with the proper interpretation of D, this formula can be applied to these cases also.

The above more or less qualitative statement, that the cleaner the gas is the harder it is to make it cleaner, can be restated quantitatively as follows:

Consider the total pass D split up into equal intervals of length l and consider the relation between the dust concentration entering and emerging from the jth of these intervals. In practice each interval might represent a separate Cottrell unit, the gas passing through the separate units in succession (*i. e.*, the units being connected in series). For the purpose in hand it is more convenient to rewrite eq. (**9**) in the form:

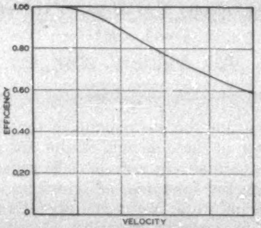

FIG. 2—THEORETICAL PRECIPITATION EFFICIENCY (PERCENTAGE REMOVAL) OF A COTTRELL PRECIPITATOR AS A FUNCTION OF THE GAS VOLUME TREATED PER MINUTE OR THE VELOCITY

$$\eta = 1 - e^{-\beta jl} \tag{10}$$

and then to substitute for $(1 - \eta)$ its value ξ, whence we have finally:

$$\xi = e^{-\beta jl} \tag{11}$$

as the formula to be used. Next if we denote by q_j the concentration of the dust leaving the jth segment of length l, and by f_j the fractional part which q_j is of the concentration q_{j-1} *entering* the interval, we have:

$$f_j = q_j/q_{j-1} = e^{-\beta jl}/e^{-\beta(j-1)l} = e^{-\beta l} = \text{const}_1 \tag{12}$$

In other words: *the fractional part of the dust passing (unprecipitated) through any pass of a series of identical Cottrell passes is the same for every pass.*

If we denote by p_i the fractional part of the dust precipitated in any pass, we have also, since $p_i = 1 - f_i$:

$$p_i = (1 - f_i) = 1 - \text{const}_1 = \text{const}_2 \qquad (13)$$

that is to say *the fractional part of the dust precipitated in any pass of a series of identical Cottrell passes is the same for every pass.*

In practise this means that if the first pass of a series of passes takes out 70 per cent of the dust entering it, the second pass will take out also 70 per cent of the dust *entering it*, but 70 per cent of the 30 per cent of the original dust leaving the first pass and entering the second; the third pass will take out also 70 per cent of the dust entering it but 70 per cent of only the 9 per cent of the original dust leaving the second pass and entering the third; etc.

View of Set-Up Used in Experimental Study of Electrical Precipitation

From the point of view of the dust concentration *leaving* successive passes, the relations become still simpler, the first pass *transmits*, for example, in the above case 30 per cent of the dust entering it; the second pass 30 per cent of the dust entering it but 30 per cent of 30 per cent of the original dust; the third pass transmits 30 per cent of 30 per cent of 30 per cent of the original (entering) dust, etc.

Gathering these results in a table we have:

Pass	In	Down	Through
1	100.0%	70% of 100.0% = 70.0%	30% of 100.0% = 30.0%
2	30.0%	70% of 30.0% = 21.0%	30% of 30.0% = 9.0%
3	9.0%	70% of 9.0% = 6.3%	30% of 9.0% = 2.7%
4	2.7%	70% of 2.7% = 1.89%	30% of 2.7% = .81%

From the point of view of costs, after the first 70 per cent has been removed, it costs just as much to take out the next 21 per cent as it did the first 70 per cent, and then as much again to take out the next 9 per cent as it did the first 70 per cent, and so on. Of course to most engineers this is a familiar case, since there are numerous other devices which obey the same economic law.

Let us now turn to an examination of Fig. 2. As already stated, this curve exhibits the relation between the precipitation efficiency and the gas volume treated (per unit time). Since the latter is proportional to the velocity of the gas in the treater Fig. 2 also exhibits the relation between the precipitation efficiency and the *velocity* of the gas in the treater.

From this curve it is readily seen that the rating of a Cottrell treater in terms of the gas volume alone is meaningless, since the rating depends on the desired efficiency, which in turn depends on the dust content of the original gas and the desired cleanliness of the treated gas. That is to say, if a customer is satisfied with dirtier gas, the rating of the treater can be increased, and *vice versa*.

A further series of deductions which can be made from the above fundamental formulas, namely eqs. (**7**), (**8**), and (**9**), concerns the effect of the *manner of connection* of Cottrell units on the resulting precipitation efficiency. In practise, of course, for well-known reasons, a Cottrell treater is not made in the form of a single large unit, but of a number of smaller units, and in installing these the question naturally arises whether there is any advantage (as regards precipitation efficiency) in connecting them in series over connecting them in parallel; or whether perhaps a series-parallel connection is better, etc. In particular, for example, if six units are available they can be connected symmetrically in four different ways as shown in Fig. 3 and designated *A*, *B*, *C*, *D*.

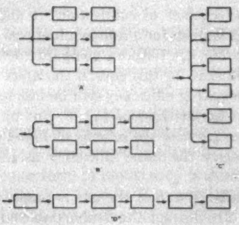

Fig. 3—Four Methods of Connecting Symmetrically Six Cottrell Passes as Regards Gas Flow

In general, if there are available a total number N of passes, such that $N = mn$, where m and n are any two integral factors of N, then it is obvious that the installation can be connected so that it consists of m units in parallel where each unit consists of n passes in series, or n units in parallel, where each unit consists of m passes in series.

In order to answer the question raised above, we have only to note that the fundamental variable which determines the cleaning efficiency is the treatment time t, *i. e.*, the length of time the gas remains in the precipitator. Since this quantity is equal to D/v, where D is the total distance traversed by the gas in the electric field and v is the velocity, which in turn is given by V/A, where V is the total volume treated per minute and A the total effective area of the installation, the cleaning efficiency for any two arrangements is the same provided D/v is the same for the two cases.

For the case then that we have m units in parallel each consisting of n passes in series, we have, provided we let l represent the length of each pass and a its effective area:

$$t = D/v = nl/(V/ma) = N\ (al/V), \tag{14}$$

that is to say, the resulting cleaning efficiency of the installation depends only on the total number of passes (and the total volume treated) and not on their manner of connection. For the alternative case where we have n units in parallel each consisting of m passes in series we have:

$$t = D/v = ml/(V/na) = N\ (al/V), \tag{15}$$

as before.

On the basis of cleaning efficiency alone then the four schemes of connection shown in Fig. 3 would be exactly equivalent.

It will be seen that the schemes of Fig. 3 all represent *symmetrical* schemes of connection; it might be asked what would happen for a non-symmetrical scheme such as shown in Fig. 4. Without going into details, it might be answered that for this case, if the units are left wide open, the resulting efficiency will be less for the case of Fig. 4 than for the case of Fig. 3; but by distributing properly the gas flow the scheme of Fig. 4 can be made to give exactly the same efficiency as the scheme of Fig. 3.

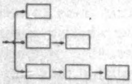

FIG. 4—NON-SYMMETRICAL CONNECTION OF SIX COTTRELL PASSES

In particular, if 1/6 of the gas is passed through the single pass, 2/6 through the double pass and 3/6 through the triple pass (by properly adjusting suitable valves), then the resulting efficiency theoretically will be the same for Fig. 4 as for Fig. 3.

Here again what we have said for Cottrell cleaners ought to hold also for wet washers or bag filter installations, or any other type of cleaner which satisfies our fundamental assumptions.

II. EXPERIMENTAL STUDY OF THE COTTRELL PROCESS

Unfortunately the theory developed above does not give us the precipitation efficiency in terms of all the fundamental variables involved in the Cottrell process; that is to say, we have had to predicate always that certain conditions remained constant; for example, the curve of Fig. 1 would hold for a particular gas and fume in a particular treater, whereas if the nature of the gas, nature of the fume, spacing of discharge electrodes, operating voltage, etc., were changed, our formulas give us no inkling of how the precipitation "constant," that is, the quantity α in eq. (4) would change. Strictly speaking, the theory developed above indicates how the precipitation efficiency varies with the treatment time, *all other conditions being constant.* For this reason, in the experimental portion of this work, it is necessary to follow a slightly different procedure than would correspond to a direct verification of the theoretical formula.

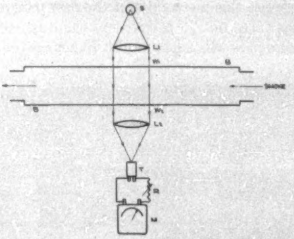

FIG. 5—SCHEMATIC DIAGRAM OF LABORATORY SMOKE CONCENTRATION METER

To begin with we shall have to list those variables which are known by experience to enter in, and determine experimentally how they affect the precipitation efficiency. We shall also verify the validity of our theoretical formulas for the conditions under which they are assumed to hold.

The selection of these variables requires some knowledge of the Cottrell process. We might list: the (secondary) operating voltage, the (secondary) current, the gas velocity, the length of the treater, the size of the discharge electrode, the spacing of the discharge electrodes, spacing of the discharge electrode to collecting electrode, the nature of the fume treated, the nature of the gas carrying the fume (last including temperature and pressure).

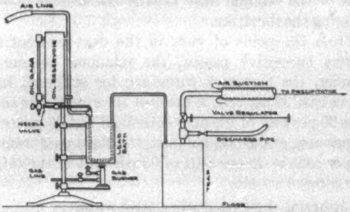

FIG. 6—SCHEMATIC DIAGRAM OF SMOKE GENERATOR USED IN THE EXPERIMENTS

Of course it is not necessarily true that all these variables are independent or fundamental; that is to say, the size of the discharge electrode or the voltage might enter in only as they affect the current flow; and it might be possible to express the whole process in terms of a few fundamental variables such as the space current, the electric field, the velocity, and the mobility of the fume particles in the particular gas.

However, since the effect of the fundamental variables might be difficult of direct verification, the procedure in the present study has been to determine the effect of the secondary variables (voltage, current, etc.) directly on the precipitation efficiency and also to determine the interrelation between the secondary variables; for example, the effect of the voltage on the precipitation efficiency is determined directly, and, also, for example, the relation between the voltage and current is determined independently. With this prelude we can proceed to the experiments.

Development of the Method of Measuring the Concentration of Suspended Material in Smokes, Fumes and Mists

Possibly the reason so little has been done heretofore in the experimental study of the Cottrell process was the lack of a suitable means of measuring quickly and accurately the concentration of the suspended material entering and leaving the experimental precipitators.

Close-Up of Experimental Precipitation and Smoke Recorder

Heretofore, the only method available for this purpose was the rather tedious and inaccurate filter method, in which a measured volume of the gas is drawn off through a filter and the resulting deposit weighed. Theoretically this process sounds simple enough, but in practise it is attended with many difficulties tending to produce inaccuracy, furthermore, the method is very tedious, and finally, the result is only an *average* value over a considerable time interval. Where many experiments have to be carried out, as was the goal in our present study, the filter method is too slow even if it were sufficiently accurate.

We set ourselves the problem of developing a rapid (in fact, instantaneous) and accurate method of determining the *concentration* of suspended material in gases. In the following we shall refer to the resulting instrument as the *smoke concentration meter*, now to be described.

The development of the instrument and a study of the principles underlying it was a considerable task in itself, and since the fundamental principles involved and a form of the instrument have been described elsewhere,[8] in the present work we shall confine ourselves to a brief description of the method and apparatus used.

Briefly the instrument depends on the fact that when a beam of light is passed a fixed distance through a gas containing suspended material, the fractional part of the light transmitted depends on the concentration of the suspended material. In particular it can be shown that if L_o is the intensity of the light *entering* the smoke-laden column of gas, L the intensity *emerging*, x the length of the column, and m the concentration of suspended material, (expressed, of course, in weight of material per unit volume) then we have the relation:

$$\log (L_o/L) = kmx$$

where k is a constant which depends, however, on the nature of the material (only on the grain size in the case of *opaque* material, but also on the wave length of light used and on the optical properties of the suspended material in the case of semi-opaque material such as acid and oil mists).

In the case of electric precipitation studies one is interested usually not so much in the actual concentrations (in grams per cubic meter or grains per cubic foot) as in the *ratio* of concentrations, as appear, for example, in our fundamental formula (2). It is then not necessary to make an absolute calibration of the meters, but more convenient to choose an arbitrary unit, which in our particular case we chose as that concentration for which over a two-inch path, 100 log (L_o/L) is equal to unity. It will be seen that this is a very convenient unit to operate with where this type of meter is used, since in order to get the concentration (in terms of this arbitrary unit), it is necessary only to subtract log L from log L_o and multiply the difference by 100. In fact, in our particular case we kept L_o at a constant value and prepared a chart which gave us the concentration in terms of the observed L directly.

The particular form of meter used is shown diagrammatically in Fig. 5. In this, B represents a long rectangular box, with two glass sides W_1, W_2, through which passes lengthwise the smoke-laden gas to be measured. The box is made long so that the gas (and smoke) will distribute itself uniformly between the windows W_1, W_2. Perpendicularly to the axis of this box and on an optical bench is set up an optical system consisting of a light source S, a lens L_1 which renders the light from the light source parallel, after which it passes as a parallel beam through the window W_1, the smoke-laden gas, and the exit window W_2, whence a second lens L_2 reconcentrates it on a light sensitive element T (a thermopile) which in turn sends a current I (proportional to the amount of light L falling on it) through the milliammeter M.

Careful experimental investigation showed that the current developed by the thermopile T was rigorously proportional to the amount of light L falling on it, so that we can put:

$$\log (I_o/I) = \log (L_o/L) = kmx \qquad (17)$$

The setting corresponding to L_o, namely I_o, is made (with no smoke in the apparatus) by adjusting a series resistance R in the thermopile circuit. As above stated I_o is adjusted to a constant value and to facilitate the work the concentration (in arbitrary units) is read directly from a previously prepared chart.

Two such meters are used; one on the inlet and the other on the outlet side of the precipitator.

The "Smoke" Generator

Prerequisite for experiments of this type is a constant and controllable source of smoke of constant characteristics. The development of this element of our set-up was also no small task. Furthermore, it was desired to produce a smoke which would not deposit on the windows of the smoke meters and thus coat them over, since otherwise the meters would read inaccurately. As might be inferred, the production of the required smoke generator was successful only after considerable experimentation with various substances and design of generators.

Ironically, while it is fairly easy to produce smoke, it is by no means an easy task to produce a *constant* source of smoke of *constant* characteristics, *i. e.*, to produce a smoke both the quantity and quality of which are controlled, and furthermore one which will not coat the windows of the measuring apparatus.

After much experimentation the scheme finally adopted was a modified form of the one originally developed by Tolman[9] and his colleagues in their experimental study of smokes. The "smoke" strictly speaking, mist-generating apparatus is shown in Fig. 6. The material "smokefied" was lubricating oil just as in Tolman's work. The principle of operation is that oil is dropped at a regulated rate into a copper U-tube immersed in a lead bath maintained at a temperature of 480 deg. cent. by means of a Bunsen burner and thus vaporized, while a stream of air is blown simultaneously through the U-tube, this air stream recondenses the oil in the form of a fine mist and serves to carry it out of the apparatus.

The amount of oil and air fed into the apparatus is carefully controlled and duplicated by means of needle valves fitted with graduated dials. The function of the various parts of the smoke generator will be clear from the accompanying figure.

Inserted between the generator and the electric precipitator, however, is a galvanized iron tank which serves the double purpose of an equalizer or mixer and a trap for the larger droplets. This tank is provided with two valves by means of which the amount of smoke fed into the precipitator is regulated, the unused portion being allowed to escape to the outer air.

By duplicating the air pressure (read on a manometer) and the oil feed, as well as the temperature of the bath, smoke of uniform quality and quantity is produced, the exact concentration required being regulated by means of the gate valves on the mixer tank.

Furthermore, our last requirement of a smoke which will not coat over the windows is realized, because in practise the windows take on a transparent film of oil of constant thickness, the excess simply draining off. The absorption by this film, of course, is corrected for by making the I_o setting with the oil film present.

The Experimental Electric Precipitator

The precipitator used in the experiments to be described below is shown diagrammatically in Fig. 7.

It consists of a horizontal iron pipe, through which the smoke-laden gas flows as shown by the arrows, with a discharge electrode in the form of a wire extending along the axis of the pipe and supported by means of insulators (made of Pyrex cane) bent in the form shown. The wire is adjusted to center by sighting through four sets of peep sights and adjusting the insulators. The high tension current is supplied by the lead-in, which enters through a Pyrex bushing (made of Pyrex capillary tubing). The effective treater length is from the center of the inlet pipe to the center of the outlet pipe. If desired, the length of discharge electrode can be fixed exactly by slipping a tube over the wire, thus limiting the distance over which corona forms.

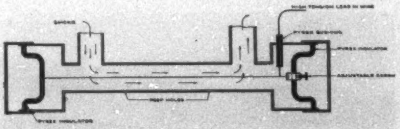

FIG. 7—SCHEMATIC DIAGRAM OF THE ELECTRIC (COTTRELL) PRECIPITATOR USED IN THE EXPERIMENTS

The precipitator is set on a slight incline so that the precipitated oil runs out of the precipitator pipe and into the end bells from which it is removed from time to time.

The High-Tension Generator

It would be desirable to use high-tension direct current for the experiments; however, since this is difficult to generate, we chose pulsating alternating current rectified by means of a kenotron. While in commercial installations mechanical rectification is employed, the mechanical rectifier with its attendant sparking complicates the phenomena by introducing considerable high frequency into the circuit. However, a more serious drawback is that with mechanical rectification a considerable and variable fraction as high as half of the secondary voltage is across the mechanical rectifier, and this fact complicates the voltage measurement. In the case of the kenotron it may be assumed that there is a negligible drop across the kenotron during the transmitting cycle, so that the secondary voltage can be calculated from the applied primary voltage or in most cases the phenomena can be expressed directly in terms of the primary voltage, to which the secondary voltage is simply proportional.

The secondary current was measured by means of a direct current milliammeter. It would have been better, of course, to use double-wave rectification, however, it is not likely that the phenomena would be essentially different, and we chose single wave rectification for the sake of economy.

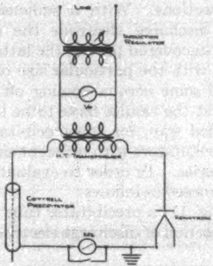

FIG. 8—DIAGRAM OF HIGH-TENSION CIRCUIT EMPLOYED IN THE ELECTRICAL PRECIPITATION EXPERIMENTS

A wiring diagram of the high tension circuit is shown in Fig. 8. The kenotron was rated at 30,000 volts, 100 milliamperes, although only about 1 milliampere was used in the experiments. The voltage applied to the primary of the high-tension transformer was regulated with an induction regulator.

The amount of gas passing through the precipitator was determined by means of an orifice meter, the differential across the orifice being measured by means of a draft gage.

The set-up consisted of (1) the smoke generator, (2) the equalizer trap, (3) the orifice meter, (4) the inlet concentration meter, (5) the precipitator, (6) the outlet concentration meter, (7) an exhauster to draw the air through the system, (8) an outlet to the stack for the waste gas; all in series.

In setting up the apparatus extended use was made of the laboratory supports and supplies furnished by the Gaertner Scientific Corporation of Chicago, whom we wish to thank for the excellency and usefulness of this apparatus. In particular, for example, the concentration meters were made by mounting light source, lenses, etc., on Gaertner optical benches; the boxes of the meters, the precipitator, the orifice meters, piping, etc., were mounted on Gaertner universal laboratory supports, which were found extremely useful and convenient.

III. EXPERIMENTS ON ELECTRIC PRECIPITATION PROPER

The use of an oil mist in these experiments in place of a dry fume has three great advantages which need to be emphasized:

First, a practical difficulty encountered in precipitating dry dust, metallurgical fume, etc., is that after the material reaches the collecting electrode it does not necessarily stay there but may be blown off by the gas stream or thrown off by the electric (coulomb) force exerted on it by the charge on the collecting electrode (it is of course a well-known fact in electrostatics that an element of area of a charged surface is subjected to a repulsive force numerically equal to $4\pi\sigma$, where σ is the surface density of charge). In such cases the precipitation proper is masked by this phenomenon. By the use of a liquid such as oil, it is assured that all the material which reaches the collecting electrode is held fast there, that is to say, it is assured that one is dealing *purely* with electric precipitation.

Secondly, in the precipitation of certain dry (dielectric) materials, as soon as these deposit on the collecting electrode, the latter exhibits corona also due to the local overstressing of the field by the dielectric material. This phenomenon, known in precipitation parlance as "back corona," is obviated in our case by the use of a liquid, in particular by the use of an oil.

THE SMOKE GENERATOR

Thirdly, when dry fume is precipitated, as the process goes on, a layer of material is built up on the collecting and also on the discharge electrode, these layers, even if they do not exhibit back corona, progressively change the electrical conditions. This is obviated also by the use of oil, for the latter drains continuously away and leaves a certain equilibrium thickness of film on both electrodes, which film then remains constant. The high degree to which results could be duplicated in the experiments described below attest to the effectiveness of this step. Also, of course, the use of oil obviates having to clean out the apparatus mechanically, since the accumulated oil drains out by itself.

1. *Relation between the outlet and the inlet concentrator.* According to our theory above, in particular eq. (**2**), the ratio of the outlet to the inlet concentration, other factors being constant, should be constant; that is to say, if the inlet concentration is varied, the outlet concentration should vary in proportion.

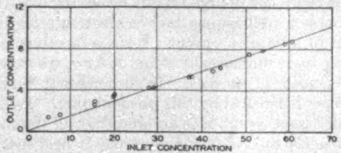

Fig. 9—Relation of Outlet Concentration to Inlet Concentration in the Experimental Precipitator

In Fig. 9 the experimental results obtained in this connection have been plotted. They show that over a considerable range proportionality indeed exists between the outlet and the inlet concentration. This fact greatly simplifies further experimentation, since except in special investigations the subsequent experiments can all be carried out at a single conveniently chosen concentration.

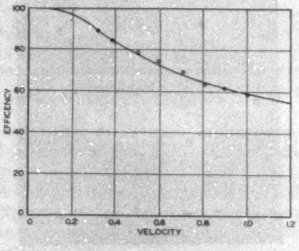

Fig. 10—Experimental Efficiency-Velocity Curve. Compare with the Theoretical Curve of Fig. 2

In particular, also, this experiment establishes the uniqueness of the quantities ξ and $(1 - \xi)$ or η; and justifies the use of the term "precipitation efficiency," since this is now experimentally proved to be independent of the concentration.

2. *Relation between the precipitation efficiency and the treatment time.* Since the treatment time is difficult of direct measurement and in practise is directly proportional to the length of pass and inversely proportional to the velocity, we shall discuss the phenomenon in terms of the latter two quantities, (see below).

3. *Relation between the precipitation efficiency and the length of pass.* While strictly speaking, in order to determine the relation between the precipitation efficiency and the length of pass, the length of the precipitator tube itself would have to be varied, in a *tube* treater the effective length of the treater can be varied also by varying the effective length of the discharge electrode. This can be done with the apparatus of Fig. 7 by slipping a tube over a definite section of the discharge electrode, thus cutting down the corona. For convenience, however, in place of a tube, slotted aluminum cylinders (large size aluminum wire) is slipped over the discharge electrode in sections. With a sufficiently large wire covering the discharge electrode the corona can be limited to the uncovered part of the latter. We found, however, that with the particular size of wire we used, there was still some corona coming off the aluminum sections, so that the results have to be interpreted in a slightly modified way, for the precipitator really consists of two precipitators with different sizes of discharge electrodes in series. In order to evaluate this case it is necessary to proceed as follows:

Consider (Fig. 11) a precipitator tube of total length D, of which a section of discharge electrode of length x is of one diameter, while the remainder of length $(D - x)$ is of another. Let q_o denote the concentration entering the first section; q_1, that leaving the first and entering the second; and q_2 that leaving the second. Then we should have the relations:

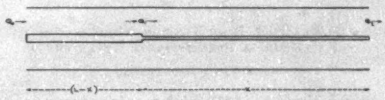

Fig. 11—Method of Limiting Effective Length of Discharge Electrode

$$q_1/q_o = e^{-\alpha_1(D-x)} \quad \text{and} \quad q_2/q_1 = e^{-\alpha_2 x} \tag{18}$$

from which by direct multiplication we obtain:

$$q_2/q_o = e^{-\alpha_1(D-x)-\alpha_2 x} \tag{19}$$

or taking logarithms:

$$\log (q_2/q_o) = -\alpha_1 D - (\alpha_2 - \alpha_1)\, x \tag{20}$$

Since all quantities except x on the right hand side of (**20**) are constant we can put:

$$\log (q_2/q_o) = c_1 - c_2\, x$$

In other words for a precipitator of this type, provided the inlet concentration is held constant, the logarithms of the observed $(1 - \eta)$'s when plotted against the corresponding exposed lengths of discharge electrode should fall on a straight line. The slope of this line furthermore represents logarithm of the ratio of the concentration leaving a section of unit length of the precipitator to that entering it.

The experiment is then to hold the inlet concentration constant and vary the exposed length of discharge electrode by slipping sections of (slotted) larger wire over it. In particular, 4-in. lengths of aluminum wire 0.125 in. in diameter were slipped over a discharge electrode 0.023 in. in diameter.

The experimental results obtained are exhibited in Figs. 12 and 13. In the first of these the logarithm of $(1 - \eta)$ is plotted against the exposed length of discharge electrode. It is seen that except for very short lengths of discharge electrode, the logarithm of $(1 - \eta)$ under these conditions is indeed a linear function of the length of discharge electrode as demanded by eq. (**21**), which it will be noted is a direct consequence of the fundamental law expressed by eq. (**2**). In order to exhibit these results in a way more in accordance with Fig. 1, in Fig. 13 the observed efficiencies have been plotted directly against the exposed length of discharge electrode, the circles representing the experimental results and the full line the theoretical exponential curve which best fits the data. It will be seen that the agreement is very close except for very short lengths of discharge electrode, hence we can conclude that the *precipitation efficiency is an exponential function of the length of pass* as demanded by eqs. (**7**), (**8**) and (**9**).

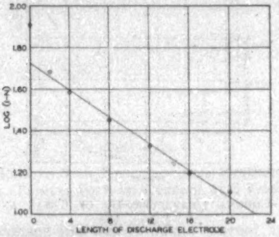

FIG. 12—TEST OF WHETHER THE EXPERIMENTAL EFFICIENCY-LENGTH OF PASS CURVE IS AN EXPONENTIAL

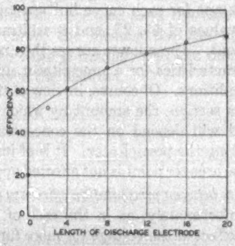

FIG. 13—PRECIPITATION EFFICIENCY AS A FUNCTION OF LENGTH OF PASS (LENGTH OF DISCHARGE ELECTRODE) IN EXPERIMENTAL PRECIPITATOR

Circles denote experimental points; full line the theoretical exponential curve

4. Relation between precipitation efficiency and the velocity of the gas in the treater. Since the exact velocity is not of great interest but merely the law of variation of the efficiency with the velocity, for convenience in the curves in place of the velocity the square roots of the pressure differentials across an orifice plate inserted ahead of the experimental precipitator have been plotted. The square root of this differential is of course proportional to the velocity. According to theory the efficiency-velocity curve should have the same general form as the curve exhibited in Fig. 2. In Fig. 10 the experimental values obtained have been entered as the small circles, while the full drawn curve represents the theoretical exponential curve which best fits the data. It is seen that the agreement here between theory and experiment is very perfect.

5. Relation between precipitation efficiency and the secondary current. It will be noted that our fundamental relation, namely eq. (**2**), involves the quantity i, which was defined as the concentration of the ions. This quantity can be considered under a given set of conditions (ionic velocity) as proportional to the space current in the precipitator. If the latter does not vary from point to point *lengthwise* of the precipitator we may take i proportional to the (total) secondary current, in which case the precipitation efficiency would be also an exponential function of the secondary current. Unfortunately, however, it is not possible directly to vary the secondary current in a precipitator without simultaneously varying the voltage, hence we must be satisfied with the determination of the relation between the precipitation efficiency and the secondary current *with the voltage also varying.* The exponential curve obtained in this connection is exhibited in Fig. 14. It will be seen that it does resemble an exponential (compare Fig. 1), although careful analysis shows that it is not a pure curve of this type.

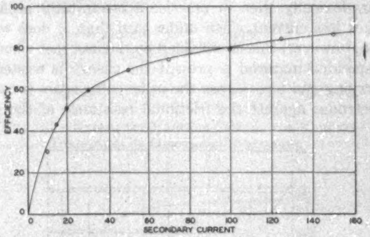

FIG. 14—PRECIPITATION EFFICIENCY AS A FUNCTION OF THE SECONDARY CURRENT (CURRENT VARIED BY CHANGING APPLIED VOLTAGE)

It was noted, however, in taking these points that the secondary current itself, and to some extent the secondary voltage, also, was affected by the *concentration* of the smoke entering the precipitator; it was noted, for example, that the admission of smoke to the precipitator always resulted in a drop in the secondary current, and that this drop increased with the concentration of the smoke admitted. This led to a special study of the secondary *current* (smoke) *concentration* relation now to be described.

6. Relation between the secondary current and the (inlet) concentration of smoke. The phenomenon mentioned just above was studied quantitatively. For this purpose the inlet concentration of the smoke was varied in definite steps and the corresponding secondary currents (primary voltage being constant) were noted.

The experimental results are exhibited in Fig. 15. Here again the experimental points are entered as small circles while the theoretical exponential curve which best fits the data is drawn as the full line. It is seen that the fit is fairly good, but still not perfectly exact, pointing to some disturbing factor.

The explanation of this phenomenon is simple. The admission of smoke results in the formation in place of the very mobile gas ions present in the clear air, of the much less mobile and slower moving charged oil drops with a corresponding decrease in the speed of transfer of charge between electrodes, *i. e.*, reduction in current. Paradoxically then in practise a precipitator actually takes less current when under load than it does when idle; however, this is explained by the fact that when no suspended material is present the energy is wasted in carrying gas ions across the intervening space between electrodes against the frictional resistance of the gas.

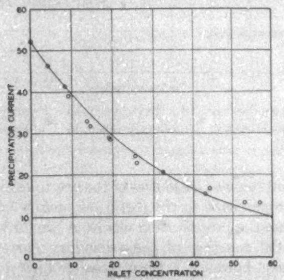

FIG. 15—SECONDARY CURRENT AS A FUNCTION OF THE CONCENTRATION OF THE SMOKE ENTERING THE PRECIPITATOR

Small circles represent experimental points; the full line a theoretical exponential curve

Incidentally, of course, the question also arises whether the secondary voltage is modified by this phenomenon. We tested also this point by connecting a Braun electrostatic voltmeter across the precipitator, and it was noted that there was an *increase* in secondary voltage simultaneously with the *decrease* in the secondary current as might be expected.

7. Relation between secondary current and primary voltage (corona characteristic). The relation between the current and voltage for the case of concentric cylinders for air is of course well known. However, in view of the results of the previous sections it becomes of interest to examine how the corona characteristic of such a system is modified by the presence of a dispersoid. Accordingly, characteristic curves of the particular precipitator were obtained with clean air and smoke-laden air in the precipitator.

The results are exhibited in Fig. 16. In this figure the upper curve 1 represents the corona characteristic for clean air or gas; the other three the same for various definite concentrations of smoke- or mist-laden air. The latter were obtained by keeping the inlet concentration constant for each curve but assigning to it the successive values of 55, 25, and 8 arbitrary units (of concentration). These lower curves then represent the corona characteristics for a precipitator under various working conditions. Of course, in view of the results of the previous section, the amount by which the current is depressed will depend on the concentration of the smoke entering the precipitator. It is of importance to note that the arcover point is not affected appreciably.

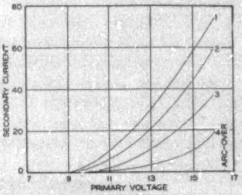

FIG. 16—CORONA CHARACTERISTIC OF CLEAR AND SMOKE-LADEN AIR

Curve 1 for clear air, lower curves for successively increasing concentrations of smoke

8. Relation between precipitation efficiency and primary voltage. Unfortunately, as in the case of the current curves, the effect of the voltage (or more fundamentally the electric field within the precipitator) cannot be determined directly, since a change of the voltage involves a change of the current also as already noted in a previous section. It is of interest nevertheless to determine how the precipitation efficiency varies directly with the applied voltage.

The results of the experiment are exhibited in Fig. 17. It will be noted that the curve also partakes of the general nature of an exponential. It will be seen that no precipitation occurs until the voltage reaches about 9.3 volts. This is explained by the fact that for the particular wire used the corona current does not begin (Fig. 16) until this voltage is reached. The curve then rises almost linearly, but eventually bends over much like the curve of Fig. 1, and ends abruptly at the arcover voltage. This curve is very similar to that obtained by Horne. However, it must be emphasized in connection with this curve that the relation is not a fundamental relation because the current is also allowed to vary (compare section 11).

9. Relation between precipitation efficiency and power input. Since it is not possible to vary current and voltage independently in a given precipitator, it is of interest to study the precipitation efficiency as a function of the power input. For this purpose, while this procedure is not rigorously correct, we formed the product of the primary voltage and the secondary current and took the result as proportional to the power input.

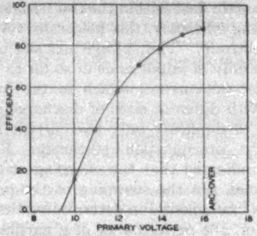

Fig. 17—Precipitation Efficiency as a Function of the Applied Primary Voltage (Current Also Varying)

The experimental results are plotted in Fig. 18. The curve is very similar to the efficiency-current curve. It will be seen that here also as in the case of the efficiency-pass curve, the cleaner the gas becomes the harder it is to clean it further, *i. e.*, the more energy it takes to remove the residual.

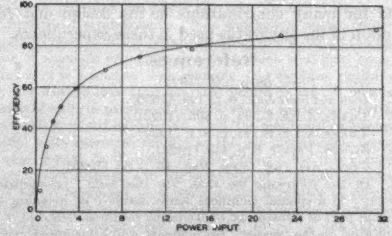

Fig. 18—Precipitation Efficiency as a Function of Power Input into the Precipitator

10. Effect of diameter of discharge electrode on the efficiency-voltage relation. Of great interest in connection with the design of a Cottrell treater is the effect of the diameter of the discharge electrode on the precipitation efficiency. Firstly, of course, it is well-known how the wire diameter affects the corona characteristic, in particular, that with larger wire sizes the same current is obtained at a higher voltage than with a smaller wire. The first effect is then to shift the corona characteristic, that is to change the operating voltage. Secondly, it is also well known that the size of the discharge electrode affects the magnitude of the electric field at any point within the treater tube; in particular for the same applied voltage the field in the vicinity of the collecting electrode and in the greater portion of the treater tube will be increased by using larger wires. Both effects combined tend to increase the electric field within the treater (ignoring, of course, the zone immediately around the discharge electrode). Hence by changing the wire size we have a method of changing the electric field within the treater; in particular of answering the question whether a high field and low space current or the reverse is desirable. In this and the following sections this point is studied in detail.

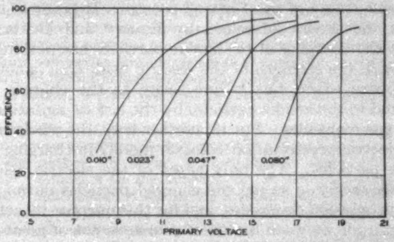

Fig. 19—Efficiency-Voltage Curves for Various Diameters of Discharge Electrode

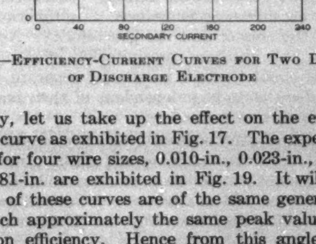

Fig. 20—Efficiency-Current Curves for Two Diameters of Discharge Electrode

Firstly, let us take up the effect on the efficiency-voltage curve as exhibited in Fig. 17. The experimental results for four wire sizes, 0.010-in., 0.023-in., 0.047-in. and 0.081-in. are exhibited in Fig. 19. It will be seen that all of these curves are of the same general shape and reach approximately the same peak value of precipitation efficiency. Hence from this angle *there is apparently little to be gained by changing the wire size, the result is only to shift the phenomenon to a different voltage range.* This indicates that the voltage *insofar as it determines the electric field within the treater volume is of little importance*—a highly interesting result—all the more so when it is considered that the voltage did not enter into our fundamental deductions. It would seem then that the voltage enters in only as it determines the current flow, and we shall next study the phenomenon from this angle.

11. Effect of size of discharge electrode on the efficiency-current relation. The rather remarkable result obtained in the previous section suggests plotting the efficiency for various wire diameters in terms of the (secondary) current flowing in the treater. The experimental results for two wire sizes, namely 0.010-in. and 0.017-in. are plotted in Fig. 20. They show that *the current alone is the determining factor;* that is to say, if the current flow is duplicated (with different sizes of discharge electrode) the efficiency is duplicated—a very remarkable and important result, particularly as regards the theoretical interpretation of the Cottrell process. It tends to support the theory advanced by Hauer[10] and Deutsch.[11] that the charging of the smoke particles has nothing to do with the strength of the electric field, *i. e.,* is not an influence effect, but is due solely to the charges imparted to the smoke particles by the kinetic agitation of the gas molecules. Put in another way, the whole trick of electric precipitation consists merely in charging the dust particles. The only effect of the electric field is subsequently to sweep the charged particles out of the space between electrodes, and for this purpose its actual magnitude between limits, of course, is not of great importance. The result also supports our theoretical deductions, since our fundamental assumption was that the whole process could be treated on the basis of chance encounters between ions and smoke particles, and that this chance of encounter was not influenced by the electric field.

IV. SUMMARY

On the basis that the chance of a dust particle being precipitated depends on its chance of encountering an ion, a formula is deduced giving the precipitation efficiency (percentage removal) as a function of the length of time the gas remains in the treater. As a corollary the precipitation efficiency is deduced as a function of the length of the treater and the gas velocity. As further corollaries the resultant precipitation efficiency of a number of equal Cottrell passes (or separate treating units) is deduced to be independent of their manner of connection as regards gas flow.

An optical method of measuring the concentration of suspended material in smokes and mists, a method of generating smoke of constant and controllable quality and quantity as well as a laboratory Cottrell precipitator for studying experimentally the fundamental laws involved in electrical precipitation are described.

The relation between the concentration leaving a Cottrell precipitator, other conditions being constant, is shown experimentally to be a constant fraction of the concentration entering the precipitator. The precipitation efficiency (percentage removal) as a function of the length of pass, the gas velocity, the electric current, the voltage, and the power input is determined experimentally. It is demonstrated that these curves partake of the nature of exponentials. The current flowing in the precipitator is shown to be a function of the incoming concentration, decreasing with it according to an exponential law. Corona characteristics (current-voltage curves) of a smoke-laden gas are determined and shown to be different from that obtained in clean air or gas. It is shown that the voltage insofar as it determines the electric field within the treater has little effect on the cleaning efficiency, this holds also for the size of discharge electrode. The voltage and size of discharge electrode are only of importance in so far as they determine the electric current, which is the fundamental variable. With different sizes of discharge electrode it is necessary to duplicate only the current in order to duplicate the precipitation efficiency. From these results it is indicated that the charging of the dust or smoke particles, not the sweeping of the particles out of the field is fundamental in determining the efficacy of the process, or, the performance of a particular treater under a given set of conditions.

V. CONCLUSION

While the present theoretical and experimental study is more extensive perhaps than any that has been made before, it is still far from complete; and it is hoped that the experiments described and experimental method developed will stimulate further research in this field.

In conclusion we wish to thank Mr. G. G. Crawford, at whose suggestion this work was undertaken, for his interest and inspiration, and Mr. H. C. Ryding for the generous support he has given us in this work. We also wish to acknowledge our indebtedness to Mr. H. Raymond for many contributions in the design and construction of the apparatus used in these experiments.

Discussion

J. C. Hale: The collected data covering work done under the auspices of Research Corporation, Western Precipitation Company, Lurgi Apparatebau-Gesellschaft, Siemens-Schuckertwerke and Lodge-Cottrell, Ltd. have been freely interchanged and it is from all these that I am drawing the following information.

As the authors have pointed out, there has not been a great amount of data presented through the engineering societies on the quantitative laws governing precipitation. One reason is that few outside of those in the development and engineering departments of the companies engaged in the application of the processes in the various industries are interested in this phase of the problems of gas cleaning. Of the large volume of data which has been collected and exchanged by the various investigators, usually only that portion has been published which has a direct bearing on some particular application.

Referring to the authors' mathematical analysis, equations (4), (5), (7), (8) and (9) are, as the authors state, various forms of the same expression. Consider equation (4); ϵ is the base of the naperian logarithm and α is a constant. I may, therefore, select a new constant K equal $\epsilon^{-\alpha}$ and rewrite this equation as

$$n = 1 - K^t \text{ or } 1 - n = K^t$$

With this simple substitution, we have the identical equation developed and reported by Anderson and his co-workers and presented in his 1919 report of tests made during that year at an experimental plant at Santa Cruz.

Equivalent formulas have been arrived at and published by European investigators, notably Heinrick and Deutsch, Engineers of the Precipitation Companies in Germany. This equation has been a most valuable contribution to the art of precipitation and it has been very extensively used. It must not, however, be regarded as inexorable. The fact that the "constant" of this equation is not always constant has served first, to stimulate the attention given by engineers in an attempt properly to evaluate it and second, to retard the publication of the results so far obtained until these results are more complete. It might be mentioned that K has been shown to vary considerably with the gas velocity. Maximum and minimum determinations of K under different conditions have shown well established variations of the order of 2 to 1. In the hands of one thoroughly familiar with its limitations, the formula is nevertheless a valuable working tool.

The mathematical analysis leading to equation (15) shows that identical efficiencies will obtain whether precipitator units be connected in series or in parallel or in series parallel with respect to gas flow provided the gas is properly divided in the cases of unsymmetrical arrangements. This conclusion serves, however, as a good example of the pitfalls to which one is led by the application of scientific principles to a field which is at least as much an art as it is a science. For example, in a problem requiring a very low friction loss, equation (15) points to the use of a large number of units in parallel. It can be shown mathematically by a somewhat involved calculation, that the combined efficiency of parallel units decreases rapidly as the gas distribution becomes unequal. Equal distribution of gas through too many parallel units is most difficult and the selection of a proper number of units to be paralleled is, therefore, not a matter of efficiency calculated on the basis of any formula, but a matter of experience with regard to distribution. Similarly, to go to the other extreme, we might be led to a design with a large number of units connected in series, to eliminate the difficulties of equalizing gas distribution. This, however, would involve a high gas velocity and material precipitated in the first of a series of units might be mechanically swept along the surface of the collecting electrode of that unit, picked up by the gas stream and carried to the following units and ultimately to the outlet main. This contingency is not considered in any formula for efficiency, but serves to indicate one of the many dangers to which scientific formulas may lead unless they are made subservient to the many requirements of different conditions met with in practise,—again pointing to precipitation as an art more than a science.

As the authors point out, the constant which appears in the formula applying to smoke concentration meters is dependent upon the grain size of the smoke particles. In spite of this statement, however, efficiency is determined in all of the tests without regard to this factor. That it is not an insignificant factor is indicated in the paper by Tolman and others, referred to by the authors. It is there stated that the light beam strength varies with the concentration of dust between certain limiting formulas in which, for small particles, the particle diameter appears directly as the cube and for large particles inversely as the first power. The Tyndall beam instrument gives, fundamentally, a measurement of visibility which is proportional to concentration only if the size of particles is a constant. A user of a precipitation installation will seldom be satisfied with an efficiency determination based upon visibility, as he requires the removal of the suspended matter from the gas stream and not merely its conversion into larger particles.

This characteristic of the concentration meter used will account for some of the errors which I believe exist in the authors' results as given in sections 8, 9, 10 and 11.

Admittedly, the filter method of measurement of concentrations gives integrated values over a period of time and is a slow, tedious process. It is our experience that it is the most accurate method and the only one acceptable as a true measurement not requiring calibration and independent of variables, such as size of particles, which influence other apparatus. Even this method has, of course, certain practical limitations in its commercial application, especially where there may be very sudden changes in gas velocity.

The smoke generator used is certainly a most ingenious and carefully worked out device. I most heartily agree with the authors' comments on the difficulty of producing a controlled quantity and quality of smoke for experimental use. That the smoke produced may vary as to size of particle is pointed out by Tolman in the paper previously mentioned.

In the absence of conclusive information as to the relative merits of half wave and full wave rectification, of locating the vacuum tube in the grounded side of the circuit or in the high potential side, and of using a mechanical rectifier, I see no reasonable objection to the use of any of these methods. The important point is that the same equipment and the same methods of measurement of electrical values be used throughout.

There are three of the authors' conclusions which lead to a difficulty if they are expressed mathematically and then compared.

Equation (3) may be written $\eta = f(i)$.

The statements in section 6 and the curve Fig. 15 may be expressed $i = f_1(c)$.

By combining these we may write $\eta = f_2(c)$.

The authors' statement in italics at the bottom of page 451 may be expressed mathematically as "η is not any function of c."

The incompatibility of these equations indicates the necessity of some explanation or qualifications of the authors' conclusions upon which they are based.

I do not believe that any general conclusion should be drawn or simple formulas of relationship established between efficiency and current voltage or power input as given by the authors in Figs. 14, 17 and 18. While these are characteristic curves applicable to some problems, there are marked exceptions which are both too numerous and too conclusive to be ignored. Many well confirmed tests on commercial installations prove that under some conditions increasing the current and power does not give any increase in efficiency.

The conclusions based on the data represented by Figs. 19 and 20 are misleading in that two important factors entering into the results exert an entirely different effect on the results obtained by the experimental equipment used and results obtainable by equipment of commercial dimensions. These factors are the limitations of the smoke concentration meter already referred to and the relatively small diameter of the pipe used.

The authors state that "the whole trick of electrical precipitation consists in merely charging the dust particles." This reduces the whole problem to the simple question of selecting an electrode assembly to give the maximum corona discharge, which is certainly a question capable of accurate scientific solution. We know, however, based upon a very wide experience in dealing with a variety of problems, that it is out of the question to draw any such an ideally simple conclusion. We have learned the futility of attempting to disregard the wide variations in other conditions. It is the existence of an almost infinite number of combinations of these variable conditions which so far removes the problem from the range of an exact science as to lead those most intimately connected with it to prefer the designation "art of electrical precipitation."

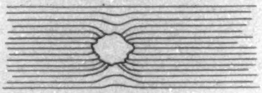

FIG. 1

Electrical precipitation has been under study and development both here and abroad for over twenty years, and from my nineteen years experience I feel that in justice to those scientists and engineers, who have during that time devoted so much research and effort to the art, the part of the authors' conclusion that refers to the possible scope of the work which has been done heretofore should be sincerely questioned.

J. J. Torok: In making some studies on precipitation some time ago I reviewed a treatise on this subject by Ladenburg which was published in the *Annalen der Physik*, 1930, Vol. 4, page 863. Herein Ladenburg presents a very interesting picture of the process of electrostatic precipitation. I believe that it would be worth while to review this at this time for it attacks the problem from a different standpoint than that taken by Messrs. Simon and Kron.

Ladenburg considers the smoke or dust as a minute particle floating in the atmosphere. This particle he assumes to have various diameters. The irregular shapes of such particles can effectively be represented as spherical. In an electrostatic field through which a large number of ions are moving the behavior of this particle will be as follows:

First assume that the particle has a dielectric constant greater than one. Under this condition the electrostatic field around the particle will be distorted. Lines of force now tend to concentrate into the particle as shown in Fig. 1 of this discussion. The ions which are moving in this field will follow very closely the direction of the lines of force of the electrostatic field, consequently they will strike the dust particles where they will be retained. Thus the dust particle acquires a charge. This charge increases until the field around the particle is distorted by the charge so that instead of the lines of force converging on the particle they now swing around it and the other ions in passing through the field will not strike the particle. In other words, the charges acquired by the particle in a particular field will increase until they repel the oncoming charges and thus it will come to an equilibrium. It can readily be seen from Fig. 2 that the larger the particle the greater the distortion it will cause in the field and consequently the larger charge it will acquire. The forces acting upon the particle, however, are proportional to the charges it acquires. Consequently, the larger particles which have acquired the greater charge will be removed from the field first. The smaller particles which have acquired less charge will require more time to be forced across the field and as a result their time of precipitation is somewhat longer.

If we assume that the dust particle has a dielectric constant equal to air there is no concentration of the lines of force into the particle, thus only the ions in whose path the dust particle lies will be entrapped upon the dust particle. This perhaps will require a little longer period of time for the particles to acquire a charge which will distort the field so that no further ions will be entrapped upon it. It is to be remembered also that under this condition the charges entrapped on the particle are less than if the particle had a higher dielectric constant.

As the size of the particle diminishes, the charge acquired by it becomes so small that the time of precipitation becomes very long. However, these smaller particles are precipitated in a period of time much less than required from a theoretical standpoint. This discrepancy is accounted for by the electric wind effect. The turbulent motion set up within the precipitator by the corona causes the air to move rapidly from one electrode to another. In this turbulent action the small particles are from time to time brought very close to the electrode and with the small motion it can obtain through its electrostatic forces it will be pulled to the plate and be deposited there.

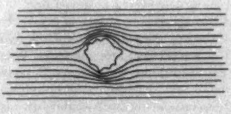

FIG. 2

From this analysis we find that in precipitators the larger particles are removed first and as time progresses the smaller particles will be taken out.

Commutation Considered as a Switching Phenomenon

BY R. E. HELLMUND* and L. R. LUDWIG†
Fellow, A.I.E.E. Associate, A.I.E.E.

THE usual commutation theories deal with the reversal of the current in the commutating coil and with means for bringing about such reversal either along a straight line or a curve. The principal object in such studies is to accomplish commutation without excessive current densities under the brush. It is recognized that frequently it is impossible to realize this, but little attention has been paid to the fact that unless such ideal conditions are obtained we actually have to deal with a switching phenomenon and that the problem should be analyzed with this in mind. The necessity for introducing the concept of switching is important inasmuch as ideal conditions can be obtained in but very few practical cases. This paper gives a brief analysis of the various considerations entering into the switching phenomena at both the leading and the trailing edges of the brush and indicates how commutator and brush burning is affected by aiding or hindering the switching operations.

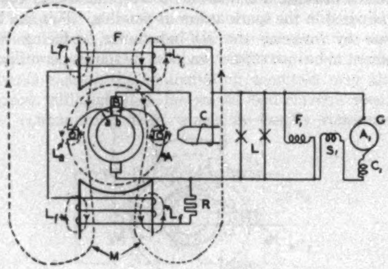

FIG. 1

Let us assume that the circuit of armature coil 1 in Fig. 1 is about to be short-circuited by brush B and that at this moment a voltage e is induced in the coil by its rotation in the commutating field, or possibly by the stator field of an a-c. machine. It is evident that sparking in the minute point or edge of the brush B which first touches the segment a will be largely influenced by the speed with which the circulating current in the coil can build up as compared with the rate of increase of the area common to the brush and the segment a. This in turn means that the speed of the commutator will have an influence as well as the rate of increase of the circulating current. The latter is determined by the voltage e and the self-inductance and resistance of the circuit of coil 1, if the coil carries no flux common to other closed circuits. This condition would exist if brush B does not short-circuit any other armature coil and if the field winding F is open-circuited, and under the further assumption that there are no secondary damping currents in the stator structure. Under these conditions, the entire main flux F and the leakage fluxes L_a cause a rather high self-inductance in the armature coil 1, and consequently a slow building up of the circulating current. Fig. 2 represents a circuit equivalent to the armature coil 1 with the assumptions made so far.

The conditions change materially if the shunt winding F is connected across the armature circuit as shown in Fig. 1, as well as across certain load circuits L and various circuits of the generator G. We now have within the armature coil a leakage reactance flux L_a and a mutual inductance M between the armature coil and the field circuit. The latter in turn has a leakage flux L_f, and it is closed partly through the armature circuit having resistance and inductance, and partly through several other circuits also having a resistance or inductance, or both; in other words, we have equivalent circuits somewhat as illustrated in Fig. 3. The rate of change in the circulating current will now depend upon all these factors, and therefore any change of constants in the field circuit or any of the other circuits may have a certain influence upon the commutating conditions. Similarly, any damping currents which can be induced in the solid portion of the stator yoke, or in coil shield or damper windings surrounding the poles, may have an influence upon commutation. The various resistances and reactances shown in the secondary circuit of Fig. 3 are replaced by a single inductance X_2 and a single resistance R_2 in Fig. 4, which while not fully equivalent to Fig. 1 somewhat simplifies the problem.

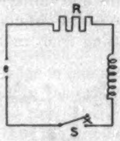

FIG. 2

All the various constants previously mentioned will also have an influence when the circuit of the coil 1 is

opened while a circulating current is still flowing in it. There will be one difference, however, in that the high leakage and self-inductances, which are helpful in the case of closing the circuit, will be harmful in the opening because they considerably increase the energy to be dissipated in the spark which forms at the trailing edge of the brush. Mutual inductance, which aids in opening the circuit as will be explained, is disadvantageous when it is closed because it allows a rapid building up of current. The effect of inductance on the opening operation may be made clear by following the switching operation in detail first for a machine with open stator circuits, wound with one coil per slot, and a brush spanning one commutator bar, so that no account need be taken of mutual inductance between a commutating coil and any other closed winding. A circulating current is assumed to be flowing when coil 1 passes from under the brush.

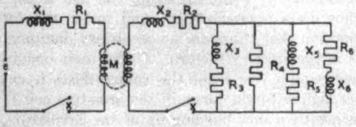

FIG. 3

When a circuit containing resistance and self-inductance such as shown in Fig. 2 is opened by the separation of contacts (the brush and the bar in this case), an arc or spark will be formed between the electrodes, because at the last point of contact the temperature may become very high and "explosions" take place at this point, giving rise to sufficient energy density to establish the cathode spot of an arc on the negative electrode.[1] As the contacts separate further the arc becomes longer and finally becomes unstable and vanishes. Any calculation of the decrease to zero of the circulating current due to commutator bars passing from under the brush must consider this short arc or spark formed. The arc characteristic, *i. e.*, the arc voltage as a function of the current through it, depends on the arc length. The latter in turn is varying and depends on the way in which the arc is lengthened as a function of time, or, in other words, on the speed of the commutator.

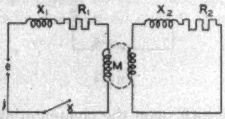

FIG. 4

If the transient arc characteristic is accurately known for a particular condition, the energy dissipated in the arc can be calculated.[2] This energy may be divided into two parts; the energy stored electromagnetically in the circuit, and the energy supplied to the circuit during the time duration of the arc. In the case of the commutating coil, the latter energy may be supplied by the voltage induced in the coil by its rotation in the commutating field, or in an a-c. machine it can also be induced by transformer action between the stator field and the coil. Usually the total arc energy will lie between the values of once and twice the energy stored in the magnetic circuit. This stored energy varies directly with the self-inductance coefficient L and the square of the current to be broken, and hence the arc energy also depends upon these factors. The length of time during which the arc or spark is present also increases with an increased coefficient of self-inductance. Since a trailing edge spark is harmful in so far as it burns the commutator and brushes, it is desirable to keep the energy to be dissipated in the spark as low as possible. This can be done by lowering the self-inductance, reducing the current to be interrupted, and also by the proper utilization of mutual inductance, which will be discussed next.

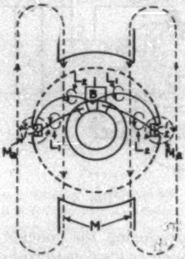

FIG. 5

As previously indicated, circuits having mutual inductance with a commutating coil are established by the field or stator circuit being closed through the armature and other circuits, or by damping currents in the stator structure. Other circuits having mutual inductance with the commutating coils usually exist if the winding is chorded, if there is more than one coil per slot, or if a wide brush is used; or, in fact, whenever the sides of at least two coils which are being commutated during a common time interval lie in the same slot. In this case the mutual inductance between coils must be considered. For example, if the brush is wide as shown in Fig. 5 and short-circuits the two armature coils 1 and 2, coil 1, which is about to be open-circuited, still has leakage fluxes L_1, but it also has mutual fluxes M with the field winding as previously described, and mutual fluxes M_a with the armature coil 2, the latter in turn having leakage fluxes L_2 of its own. This may better be

shown by the simplified although not fully equivalent circuit indicated in Fig. 6. If such a circuit containing mutual inductance in addition to self-inductance and resistance is opened with a switch, the decrease of the current in the primary circuit may again be calculated if the transient arc characteristic curve is known. It is found that in this case all of the stored energy need not be dissipated in the switch. The decrease of current in the primary circuit will induce voltages in the secondary circuits such as to cause their currents to change. This means that part of the energy stored in the primary circuit may be transferred to the secondary circuits and dissipated as I^2R loss in them or held in storage in the secondary circuits. Consequently, the energy dissipated in the spark may be, and usually is, reduced by introducing mutual inductions. The magnitude of the reduction depends on the degree of mutual coupling between the circuits, and upon the circuit constants, such as resistance and self-inductance, of all the circuits having mutual inductance with the commutating coil. It follows, therefore, that as conditions in the stator circuits change, the commutating condition may also change, although such factors as load current, speed, and commutating fields, which are usually considered as the only ones determining the commutating conditions, remain unchanged. For similar reasons, different conditions of mutual inductance between the various armature coils will have an appreciable influence. The conditions of the mutual flux M_o and leakage fluxes L_1 and L_2 in Fig. 6 will of course be appreciably different when the coils are located in separate slots and when the coils are located in the same slot. This difference leads to the frequently observed condition that certain commutator segments show more burning than others. These considerations also explain why frequently a split-throw of the armature coils improves commutation as a result of its effect upon the relation between leakage and mutual inductances of the coils. Without the split-throw a good transfer of energy from coil to coil in the same slot may take place, but the last coil in the slot is not well coupled to the first coil in the next slot and hence considerable energy must be dissipated when the circuit of the last coil in a slot is broken. The split-throw reduces this maximum dissipation of energy in the spark because at least one coil side of the coil under commutation is always closely coupled with another coil side, and, assuming that the brush is wide enough to short-circuit the adjacent coil, better transfer of energy can take place. The beneficial effect thus obtained consists not only in decreasing the maximum sparking but also in bringing about more uniform sparking on the different commutator bars, which in turn reduces irregular wear and differences in the heating of the bars; irregular heating of the bars if occurring to any marked extent is likely to cause differences in expansion of the bars and therefore mechanical irregularities in the commutator surface, with consequent further accumulative harmful effects on commutation.

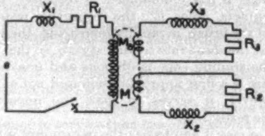

Fig. 6

In all of the previous discussions on the constants of the circuits which may influence commutation, only resistance and reactance have been mentioned. However, with the high frequencies of commutating currents, it is quite possible that at times certain capacity effects in the various circuits may exert an influence upon commutation conditions.

Having established the new concept of switching and the fact that the various machine and external circuits may have an influence upon commutation, we have found a means for explaining many other practical experiences which cannot be explained by the conventional commutation theorites. It can be readily seen, for instance, that there may be a difference in commutation between shunt, series, or separately excited machines, between laminated or solid field structures, etc., although the speed, current, and commutating field are the same. It follows that in the case of a-c. commutator machines the commutation may be affected by the size and type of transformer to which the machine is connected and by various other factors. Interesting results may be obtained with two series-connected motors on a motor car, especially in a-c. motors having no damping effects in their field structure. If in such a case the commutating impulses transformed into the fields of the two motors are exactly in opposition, no damping current can flow in the fields. Such opposition of voltages will occur if the relative position of the two commutators is such that the brush edge in one motor lines up with the mica insulation while in the other motor it happens to be in the center of the bar. If the relative commutator position changes so that the brushes in both motors will have the same position with regard to the mica insulation, the commutating impulses reflected in the fields will be in phase and damping current current can flow, thus causing conditions entirely different from those previously mentioned. With two such motors on a motor car having slightly different speeds caused by a difference in the wheel diameters, periodic variations of commutation will take place. With the two motors connected in parallel across the same transformer, similar variations may take place. Even a change in design from series to parallel connected fields in the motor may influence commutation. With such machines as phase-advancers or regulating machines connected into the secondary of induction motors, the switching theory readily explains differences in commutation which have been observed by the authors for different connections of such machines to various external circuits.

The introduction of the switching concept into the commutating problem is, of course, not necessary when ideal commutating conditions exist. There are also cases which approach the ideal sufficiently close to make the consideration of the switching concept unnecessary in practise. Again, where the commutating conditions are not ideal but where the brush short-circuits several armature coils, their mutual effect may be so predominating that the characteristics of the field and external circuits may have little influence. However, in general the commutating phenomenon cannot be considered as completely analyzed unless the possibility of the switching phenomenon as influenced by the various circuits has been given due consideration.

Discussion

Ernst Weber: I cannot quite agree with the authors in that the commutation problem has been given little attention as a switching phenomenon. On the contrary, the complete fundamental differential equations of commutation in a general case were established as early as 1908 especially by R. Rüdenberg (*E.T.Z.* 1908, page 65) following previous discussions on the problem which go back to 1905 when G. Mie and E. Arnold derived a mathematical condition for good commutation which since then often has been the center of much discussion. The complete differential equations take into account all the inductive couplings of the armature coils at the point to be short-circuited, and under short-circuit conditions. In addition the inducing effects of the external fields as produced by the main poles and by the commutating poles are taken care of. The one reason why no further progress has been made in this mathematical investigation is that it is not possible in general to integrate the underlying systems of differential equations.

An excellent brief summary of the theory of commutation may be found in German Manual *Starkstromtechnik*, Vol. I, U. 494 (published by W. Ernst u. Sohn, Berlin 1930) treated by C. Trettin. The system of differential equations, when the brush covers for example four segments and thus short-circuits three armature coils, is given by:

$$\begin{aligned} i_1 r_1 - i_2 r_2 - L \frac{du}{dt} - M_{12} \frac{dv}{dt} - M_{13} \frac{dw}{dt} &= e' \\ i_2 r_2 - i_3 r_3 - M_{12} \frac{du}{dt} - L \frac{dv}{dt} - M_{23} \frac{dw}{dt} &= e'' \qquad (1) \\ i_3 r_3 - i_1 r_1 - M_{13} \frac{du}{dt} - M_{23} \frac{dv}{dt} - L \frac{dw}{dt} &= e''', \end{aligned}$$

where i_ν denotes the currents in the segments; u, v, w the respective currents in the armature coils under short-circuit condition, r_ν the resistances of the closed coil-circuits, L the self, and $M_{\nu u}$ the mutual inductances of the coils, and e', e'', e'' the electromotive forces induced by the fields in the commutation zone. If all the parameters involved were constants it would be easy to solve for the currents and to deduce theoretically their shape under any condition of external uncompensated fields. However, all the parameters are variable, such as the inductances due to saturation, eddy currents and the changing positions of the coils relative to the field system; the resistances due to the varying contact area of brush and segment, the dependence of brush resistance on temperature, contact pressure, and current density. The equivalent circuits given in Figs. 3, 4 and 6 of the paper appear, from this recognized point of view, as very rough approximations. The variation of resistance for example extends over a range from several thousands of ohms to infinity.

In view of this extreme complexity we may finally state that commutation is one of the most intricate problems of scientific engineering. To arrive at some result, it was but natural, that either restrictions in great number were imposed on the illustrative system (1) in order to fit it to the mathematical means available for a solution, or estimations were made as to the influence of the various terms when straight line commutation was set as the aim. Several of the conclusions arrived at by authors from energy relations can thus be found in the literature. In a recent book published by J. Springer, Berlin, 1929, L. Dreyfus treats the whole problem of commutation on a mathematical, rigorous, but not very convenient way. The Siemens Schuckert-Werke, (Mr. C. Trettin), Berlin, as well as L. Dreyfus, hold several patents to use damper windings in slots or as wedges in order to influence the inductance at the instants of short-circuiting and breaking the short circuit of the coils, by these means causing the electromagnetic energy to be dissipated in heat in several parallel circuits.

The variations of the inductances with time are very small contrasted with those of the resistances. Assuming that over small time intervals both parameters may be taken as constants, the transient will be of the type of an exponential curve, the time constant of which is given by $T = L'/R'$, if L' is the effective inductance for the considered interval of time. At the first instant, R' is very large, the time constant very small, the rate of change of the current large and therefore a tendency to spark. However, since the time constant increases rapidly to a finite value, the danger is not pronounced. Conversely for the breaking of the contacts, since R'', the respective resistance at the trailing edge of the brush, is rapidly increasing, the time constant will decrease at the same rate to almost zero, so that the tendency to spark at the trailing edge is obvious and unavoidable. This physical picture is a first approximation and not at all the single criterion; however, it serves to show the importance of the variation of the resistance.

In conclusion may I emphasize the paramount influence of the brush material. Practise shows again and again that cases of bad commutation, considered as hopeless by theoreticians, are satisfactorily solved by engineers who patiently try various kinds of brushes until they succeed in finding the "adequate brush" for that special case. Investigations are under way to throw some light on the action of contact resistance and its dependence on the brush material, but we are still lacking complete data on this subject.

Thomas T. Hambleton: The consideration of commutation from the standpoint of switching may not be entirely new as most designers of commutating machines must recognize commutation as a high-speed switching of armature coils. The consideration of the possible influence of external circuits is entirely new to me. Of course it is desirable to view any complex problem from as many angles as possible, and it is in this respect that the paper should prove to be of value.

I fail to see where the paper presents any new knowledge that will enable designers to produce better commutating d-c. machines. I would therefore ask the following questions:

1. Has the consideration of commutation as a switching operation resulted in a method of more accurately pre-determining the commutation performance of d-c. machines?
2. Has it indicated any change in design proportions which has produced better commutation?
3. Have any specific cases been observed where commutation in d-c. machines has proved to be affected by external circuits; field circuit, damping circuits or external load circuits?
4. Is it not a fact that the considerations set forth in this paper apply almost entirely to a-c. commutating machines?
5. Has it been possible to compensate in the design of machine for the effect of external circuits on commutation?

G. W. Penney: The usual theory of commutation is based on the assumption that the brush contact drop is the same for all bars and that every other part can be built exactly as designed, so that the current reversal can be a straight line function or some other function which would be uniform for every coil. We are all familiar with the fact that the theory developed from these simple assumptions does not explain many of the troubles encountered in practise. For example, in the case of a large 250-volt generator running at constant speed and load there is commonly one coil per slot, so that all coils are theoretically alike and therefore for any given load and speed there should be a value of interpole flux which would exactly reverse the coil current in the period when a bar is under the brush, thereby giving black commutation. And yet we know that there are many cases where even for steady load conditions there is no value of commutating pole flux which will give black commutation. If the sparking is observed with a stroboscope it will often be found that a given value of interpole flux will give sparkless commutation on certain bars, but sparking at other bars. If the interpole flux is changed slightly, the sparking will disappear at the given bars, but sparks will appear at other bars, so that when observed with the unaided eye, the sparking will appear to be constant for a considerable range of commutating pole flux.

When we consider that a relative movement of one-ten-thousandth of an inch between one bar and the adjacent bars may seriously disturb the uniformity of contact drop, or that a slight deposit of carbon on one bar may have an equally serious result, it seems unreasonable to expect to maintain a uniform contact drop at all times.

The method of analysis described in this paper when combined with the characteristics of the brush under quickly changing current density in a portion of the brush face gives a means of analyzing the performance of the coil during commutation when ideal conditions do not exist.

The ability of a machine to commutate satisfactorily when slight disturbances occur either in the contact, at the commutator or in the rest of the circuit, should be a much more valuable index of its performance in service than the conventional analysis based on perfect conditions.

C. G. Veinott: The general principles, given in the paper, of course, apply equally well to lap or wave windings but the statement that with "a brush spanning one commutator bar . . . no account need be taken of mutual inductance" does not. This is true with a lap winding but is not true for a two-circuit wave winding of four poles or more because the number of commutator bars per pole is not an integral number. The discussion to follow does not refute any of the facts presented in this paper but only supplements the latter with information on wave windings not covered in the paper.

Some time ago I studied the commutating conditions in a wave winding and obtained, by graphical integration, the curve of the reversal of current in the commutating coil against time. I came to the conclusion that, in a wave winding of 4 or more poles, when only two brush arms are used, the commutating conditions are different under the two brush arms. This is due to differences in the coupling conditions of the coils undergoing commutation. As the authors have brought out that differences in the coupling conditions affect commutation, I only need to show how the coupling conditions under the two brush arms differ.

To be specific, consider a 4-pole wave-wound, retrogressive armature having 33 slots and 33 commutator bars with the armature winding chorded ¼ of a slot. Assume two brushes spaced 90 deg. apart, each brush spanning ¾ bars. Calling the brushes positive and negative solely for the purposes of identification and not to indicate actual d-c. polarity, consider the period when the positive brush just starts to span bars No. 8 and No. 9. This condition is represented in Fig. 1. Let us ignore, in this analysis, the mutual inductive effects of the field circuit and only consider other armature coils since effects due to each other circuits would only be superimposed upon the effects we are considering. (In Fig. 1 the coils represent single coil sides, the numbers the slot in which the coil side lies, and the letter *b* or *t*, whether the coil side is in the bottom or in the top of the slot.) We observe this significant fact: the coils short-circuited by the positive brush *begin* commutation without being coupled with any other coils undergoing commutation. At this point the negative brush is merely riding upon bar No. 33.

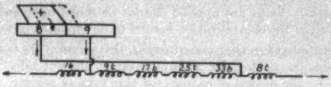

FIG. 1

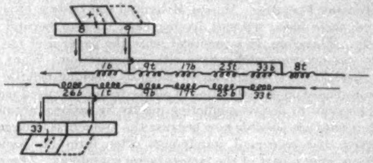

FIG. 2

In Fig. 2, we see the positive brush finishing its commutation. Observe that during the last ¾ths, including the *finish* of the period of commutation, three of the four coil sides short-circuited by the positive brush are mutually coupled with three of the four coil sides short-circuited by the negative brush at that time. It can be seen further that the coils short-circuited by the negative brush *start* commutation with three coil sides coupled.

In Fig. 3 we see the coils short-circuited by the negative brush *finishing* commutation with no coupling. At this time the positive brush is riding upon bar No. 9.

This brings out very clearly the fact that the commutation may be quite different under one brush than under the other.

If the brushes span one bar, somewhat the same conditions obtain except that the coils under the positive brush start commutation loosely coupled (one coil side coupled) and finish with close coupling (3 coil sides coupled). The coils under the negative brush start commutation closely coupled and finish commutation loosely coupled.

Considering commutation as a switching phenomenon, it follows that, when the coils under the positive brush finish commutation, if an arc is formed, all of the stored energy need not be dissipated in the arc to burn the commutator since much of this energy can be transferred through mutual inductive effects. When the coils under the negative brush finish commutation, if an arc is formed, they can transfer but little, if any, energy to other coils undergoing the process of commutation. Of course, there is always the possibility of transferring some of this energy to the armature working circuit, but this transfer of energy must be relatively small.

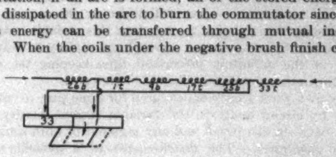

FIG. 3

F. W. McCloskey: It has become increasingly difficult of late years to predict the commutation characteristics of d-c. machines in which the loads applied are of a rapidly fluctuating nature.

Undoubtedly this is due in part, at least, to the fact which is brought out in this paper, that the customary method of figuring commutation does not embrace all the factors involved.

Street-car motors are subjected to this type of load, particularly in notching up the controller. Observations of such motors have shown that with peak currents of, say, twice the one-hour rating obtained in notching, the sparking may be in the neighborhood of twice as severe as when the same load is applied under steady conditions. It is therefore evident that stand tests in which steady loads are applied cannot be relied upon entirely as a criterion of the commutation results to be expected in service.

As pointed out in the present paper, this is one of the conditions which the usual theories of commutation do not take into account. In the design of motors for this type of service, particularly in these days of rapid acceleration of street cars, careful consideration must be given to this angle of commutation.

Thomas Linville: Messrs. Hellmund and Ludwig have presented their ideas without having carried them beyond pure theory. Therefore, in a practical sense the paper does not help solve the designers' difficulties with commutation. What must be hoped for is a commutation analysis reaching definite conclusions based on consideration of all the factors involved making it impossible to derive conflicting results by rational argument. Such results are possible now because the problem is so large and complex that restricted standpoints often form the basis for analyses, only a part of the factors being considered. The result is that many different opinions are held making confusion and disagreement.

Rising from these observations to the plane of theoretical thought in order to discuss the paper on its own level it seems that commutation has always been considered (in most of our minds and broadly speaking) as a switching phenomenon. The object has been to accomplish the switching; *i. e.*, to make and break the contact between the brush and each segment, with no current flowing. It makes little difference whether we start, knowing that the current will flow and appear as sparks if certain conditions exist, or with the premise that the current is already flowing. The objective in each case, is to prevent sparking and the analysis is likely to be the same. The possible difference is that we cannot definitely treat a sparking case mathematically as such.

In the commutation of a machine, the brush in making and breaking the contact with each segment increases and decreases the contact area at a definite rate. If in decreasing the area, for instance, the circuit conditions tend to diminish the current at a slower rate, the current density in the contact increases. This is equivalent to saying that the job of "forcing" the current change is thrown on the brush. Carbon brushes have a fairly definite limit to their ability in this connection. As the area diminishes the circuit resistance increases diminishing the current faster. If too much is demanded of the brush (if this variable component of the circuit resistance must increase too rapidly to reduce the current in the definitely prescribed time keeping the density within the limits of stability) then the brush arcs.

In my own work I have endeavored for some time to calculate, entirely by circuit analysis, the variable current density in the contact between the brush and any segment of both simple and complex machines. The development of a general method giving definite and practical conclusions now seems possible.

It is based, of course, upon the assumption of stable brush characteristics. Hence, sparking is not considered. Interesting results are promised since, for poorly commutating machines, the solution shows high current density occurring in some cases on the leading edge of the brush, more often on the trailing edge, and sometimes on both. These high current densities indicate that sparking is likely,—that it actually will occur if the density is sufficiently high. When it is determined at what density (for average conditions) the contact drop characteristic of a brush becomes unstable, or glowing and arcing begin, I expect we shall be able to say, by the calculation, when a machine will spark and when it will not. Furthermore since the circuit conditions depend upon the design dimensions it looks possible to answer by calculation many of the questions now perplexing the designers.

In one sense it does not seem that commutation should be called a "switching phenomenon" or by any name suggestive of a restricted point of view. Rather, it seems preferable to consider it always broadly as a circuit problem in which boundary conditions must be met in a fixed interval of time. Truly in the contents of the paper Messrs. Hellmund and Ludwig have considered it thus.

One point should be called to attention. In practical machines where several coils are commutating simultaneously the mutual inductances between the armature coils and the main pole windings, when taken together, have the effect of canceling one another with the result that no current is induced in the main pole windings. Hence, the external load circuits have little effect upon commutation except in particular cases. The fact that they do is a true idea but, possibly, overemphasized. The most important disturbers of good commutation are still those fluxes locally in and about the commutating slots; fluxes established by each armature coil which are not mutual with any other circuit. As suggested in the paper reducing these to improve the contact breaking conditions makes the contact making conditions worse but the balance is now, and surely always will be, in favor of the former.

R. M. Baker: The authors have exposed in this paper the very interesting observed fact that the commutation of a machine is indirectly affected by the nature of the connected load. As described in the paper, the effect is due to the change in the possible damping of the main pole windings. The results of some measurements of armature coil inductance taken with and without the field coils short-circuited; and also the maximum possible inductance of the armature coil with no damping follow:

Inductance with field coils short-circuited separately 7.28×10^{-6} henrys.

Inductance with field coils open 10.6×10^{-6} henrys.

Maximum possible inductance (calculated) 31.0×10^{-6} henrys. The machine on which these measurements were made was a 20-hp. d-c. shunt generator with frame made up from heavy laminations (0.05 inches thick), and the measurements were made at 700 cycles.

From the above data, it can be seen that for this particular machine, a change from perfect field damping to no field damping can increase the inductance of an armature coil by about 30 per cent. In a machine having a very perfectly laminated field structure, the increase would be greater, whereas if a machine has a solid yoke, the increase would surely be less. We should expect, therefore, to find the phenomena described by the authors principally in those machines having a perfectly laminated magnetic circuit.

R. E. Hellmund: Referring to the discussion by Mr. Weber, I cannot agree that the subject matter of our paper is anticipated by the work which he mentioned and the mathematical treatment given by him. It is true that the commutating phenomenon has been referred to as a switching phenomenon for a great many years. It is also true that the effect of mutual inductance between various short-circuited coils has been taken into account in a great many previous theories, including the one referred to by Mr. Weber. However, as far as I am aware, all of this previous work deals exclusively with the reversal of the current in the armature coil while it passes under the brush. All of such work is referred to in our paper as the conventional commutation theory. In contrast to these conventional theories dealing with phenomena under the brush, our paper is intended to deal only with the phenomenon at the two edges of the brush, and, more particularly, with the arcing and its effect at the trailing edge under commutating conditions which result in arcing. The theories referred to by Mr. Weber relate to our paper only in so far as they have an influence upon conditions which may be found to exist at the edges of the brush as a result of what happens during the passage of the coil under the brush.

Referring now to both Mr. Weber's and Mr. Hambleton's discussion, I can only again emphasize what is stated at the end of the paper; namely, that the material given in the paper is of practical importance only in those cases in which ideal conditions by means of the proper commutating fields can not be obtained. Since this is more frequently the case under the various operating conditions of a-c. machines than of d-c. machines, it follows directly that the considerations are of greater importance in connection with a-c. problems.

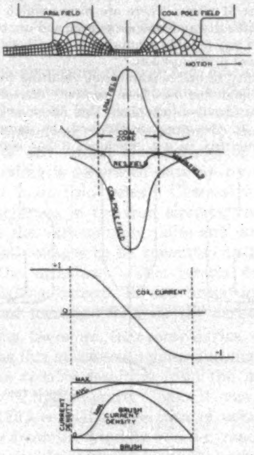

FIG. 4

Some discussion relating to Mr. Hambleton's first and second questions will be given later in connection with some figures. With regard to his third question, some cases have been observed where the commutation of a d-c. machine under actual operating conditions was different from that obtained with the test method used at times, in which the armature is short-circuited and the field excited through a high resistance just sufficient to give the desired current in the armature. In this case the damping currents in the field are of course lower than under normal operating conditions, and this may partly or entirely account for the difference noted in commutation. On the other hand, this case is further complicated by the fact that the commutating field is somewhat different under the two conditions of operation. The considerations given in the paper may also be of importance in certain machines having a third-brush or other special d-c. arrangements. In these and other cases the considerations in the paper may indicate the desirability of using the split throw in the armature, closely interlinked damper windings, etc. Aside from the fact that in most normal conditions of d-c. commutation the commutating fields can be adjusted reasonably well, there are other factors favoring the usual d-c. machines. In this connection the tests described by Mr. Baker in his discussion, which were made after this paper was written, are most interesting and somewhat surprising. They show that even in a machine with heavy laminations the damping effects of the stator may be appreciable, which in turn indicates that in machines having solid frame portions the normal damping effects may have a very favorable and predominating influence. Mr. Hambleton's fourth and fifth questions are answered by the previous remarks, as far as d-c. machines are concerned.

Referring now to a-c. machines, various examples can be cited in which the considerations of the paper have been of utmost practical importance and where a definite influence of the machine and external circuits have been noted. In several instances the change to a split throw has made sufficient difference to change practical failure to successful operation. This was especially important when for reasons other than the motor design proper the motors were built with more flux per pole than is desirable from a motor design point of view. Another practical example is that of the periodic sparking described in the paper. With certain low-frequency exciter machines for induction motors, the results when such machines were operated in connection with the induction motors were entirely different from results obtained on the test floor with resistance load. Here again the difference was very marked. These examples are also interesting because greater difficulties were experienced with 25-cycle motors than with 60-cycle motors, which is the direct opposite of what designers of a-c. commutating machinery are accustomed to. The reason for this was that in these cases the leakage reactance between the short-circuited armature coil and other circuits is made up largely of differential leakage, which in turn is proportional to the total main flux per pole. The latter was larger in the 25-cycle than in the 60-cycle machines and as a result led to less favorable commutating conditions in the 25-cycle machines.

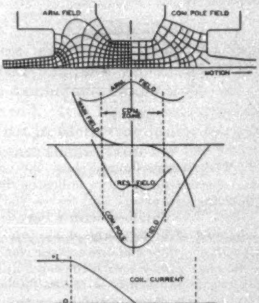

FIG. 5

The influence of external circuits in a-c. machines is also of greater importance not only because due to the highly laminated stator structure there are no damping effects in the stator core, but also because there frequently is, especially in motors for reversing operation and with consequent tilting of the carbons in their holders, only one armature coil short-circuited by the brush and consequently none of the other armature coils is able to supply any damping effect.

With reference to the question as to whether the switching operation at the edges of the brush in d-c. machines can be avoided, a brief discussion of the following figures may be of interest and may cover certain points raised in the discussions by

Messrs. Weber, Hambleton, and Penney. Ideal conditions are obtained if at the moment an armature coil is short-circuited its voltage is zero, and consequently zero current in the edge of the brush at that instant. Similarly, sparking and switching conditions at the trailing edge are impossible if the current in the edge of the brush is zero when the circuit is opened. This condition is fulfilled in Fig. 4. The armature and commutating pole fields have been carefully charted,* and it will be seen that the resultant field is zero both at the entering and trailing edge. The current in the commutating coils is shown below and has a characteristic which is sometimes referred to as "sinusoidal commutation." The bottom figures show the current density in the brush, and the minimum curve indicates that zero values apply at the time the coil enters and leaves the commutating zone. These results were obtained with a very small gap after much careful scheming with the shape of the interpole and with an armature without chording and one coil per slot.

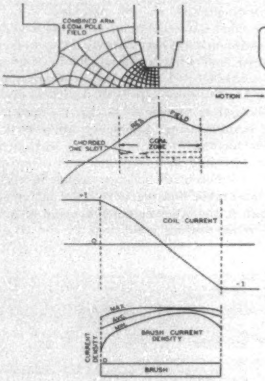

Fig. 6

Fig. 5 shows the same machine with the conventional large air-gap. The conditions are not nearly so favorable inasmuch as the resultant field induces a voltage in the commutating coil at the ends of the zone and there are certain current densities at both the entering and trailing edges. Fig. 6 shows a machine with chording of one slot and results are still less favorable; in fact, it was found impossible with chorded armature to obtain by changes in the interpole the ideal conditions shown in Fig. 4. In cases where two or more coils per slot are used, switching conditions are altogether unavoidable because, due to the influence of the main poles, the commutating field as shown in Fig. 7 is usually unsymmetrical. This means that the field cannot be correct for both coils. It is too weak for the commutation of the first coil and therefore commutation is incomplete at *b* when the first coil leaves the brush. However, on account of the close coupling with the other coil in the same slot, the energy can be readily transferred into the other coil, as indicated by the upswing of the current in the second coil. The curve for the second coil shows that because the commutating field in the range of its commutation is too strong, a reverse current is built up as indicated at *d* which has to be interrupted when the circuit opens. These figures, except Fig. 4, indicate clearly that there actually is a switching operation at the edges of the brush in most practical d-c. cases. This, however, is not of very great practical consequence in most d-c. cases for the various reasons previously indicated, although it may at times be largely responsible for the sparking which cannot be entirely eliminated.

L. R. Ludwig: In one of the discussions a question was raised regarding the feasibility of some special commutating arrangements. In answer to this, it may be stated that many such arrangements lead to irregular wear of the commutator parts, which would result in sparking regardless of any merits from an electrical point of view. There are means which would not be open to this difficulty and they have been and are being carefully considered. If any notable results are obtained, this work will be made the subject of later papers.

The possibility of bad commutation resulting from pulsations in the main field flux has been carefully investigated by us several times. In d-c. machines this effect is of minor importance due to the large air-gap and the damping effect of the stator structure. In a-c. machines it has been found that such pulsations may introduce high short-circuit voltages into the commutating coil, and consequently this point should always receive careful attention. It is the usual practise to construct a-c. machines, particularly those having relatively weak fields, with skewed slots in the rotor. Under this condition careful investigation has failed to reveal any commutating difficulties due to pulsations of the main field fluxes.

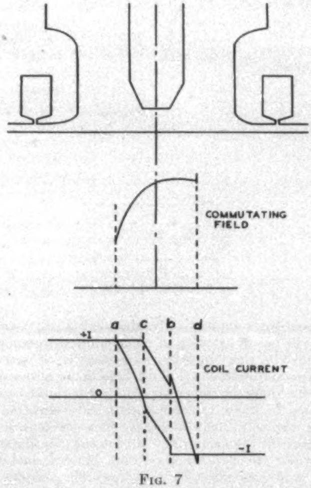

Fig. 7

The discussion given by Mr. Veinott is a valuable study of the special problems involved in a wave winding, and it again makes clear the necessity for a complete analysis of the electrical conditions existing within a commutating coil.

Equalizing Currents in the Armature of a D-C. Machine

BY ROBERT M. BAKER*

Associate, A.I.E.E.

Synopsis.*—This paper contains an analysis which shows how the equalizing currents in the armature coils of a d-c. machine act to correct the unbalance causing these currents to flow. It is shown that even with very small inequalities of main pole air gaps (plus or minus 7 per cent of an average main pole gap), the equalizing current in an armature coil may reach, several times each revolution of the armature, a peak value as high as 25 per cent of the full load coil current value. The analysis is unique in that it is based upon experimentally determined curves of equalizing current variation in an actual machine.*

INTRODUCTION

WHEN the parallel type winding was first used on the armatures of large d-c. machines it was almost impossible to obtain sufficiently good magnetic balance of the main field circuits to permit satisfactory operation. This was due to the fact that the voltage of any circuit of a parallel or lap-wound armature winding is generated entirely by the flux of two adjacent main field poles. Unequal air gaps, or unequal reluctances in the iron circuits, result in unequal flux in the various main poles and consequently cause unequal voltages to be generated in the parallel circuits of the armature. This results not only in heavy circulating current in the armature winding, but also in an increased load on the carbon brushes.

It is obvious, therefore, that some device was needed to balance the flux of the main poles automatically and overcome the trouble resulting from the unavoidable irregularities of manufacture. Thus it was that B. G. Lamme in 1896 conceived the idea of connecting together in the armature winding of a d-c. machine, those points which should normally be at the same potential. He reasoned that with these polyphase connections, currents would circulate between the various parts of the armature winding to equalize the flux of the different main poles, just as a number of synchronous machines operating in parallel tend to equalize their fluxes by causing exciting currents to flow in the armature circuits. This was the beginning of the equalizing connections or cross connections as they are used today.

Equalizing connections have proved themselves capable of taking care of considerable unbalance in the main fields, and have made it possible to build large d-c. machines to operate satisfactorily with lap-wound armatures of twenty or more circuits. Their performance has in fact been so satisfactory that very little time has been given to a study of the details of this performance. Purely theoretical analyses are valuable in giving one a clear mental picture of the process by which the equalization is accomplished; but they are always necessarily based upon simplifying and often inaccurate assumptions and are therefore of little quantitative interest. The analysis given in this paper is based upon the experimentally determined variation of equalizing currents in the armature coils and shows how these known currents act to overcome the magnetic unbalance causing them. The value of such a treatment lies in the fact that it will give the reader some idea of the magnitude and nature of equalizing currents arising from a certain unbalance in the main field circuits and will make the whole subject more tangible by showing records of the equalizing currents in the armature winding of an actual machine. It will also suggest a method for studying the subject in more detail.

THE MACHINE

The machine used in this study is a 25-hp., 4-pole, 220-volt, 1,500-r.p.m., d-c. generator. The armature is full pitch lap wound and has 40 slots, one coil per slot, ten turns per coil. It is 100 per cent cross connected on the front. That is, each commutator bar is in turn connected to another commutator bar just two pole-pitches ahead. Since the armature has 40 slots and a full pitch winding, it is entirely symmetrical. The average main pole air gap for this machine is only 0.074 inches.

ANALYSIS OF TEST RESULTS

To obtain oscillographic records of equalizing currents in armature coils it was necessary to insert a small resistance in series with the coil or coils to be studied, and to record the voltage drop across this resistance. The value of resistance chosen was only 25 per cent of the resistance of a single armature coil, and since equalizing currents are limited almost entirely by armature coil inductance, the insertion of this small resistance caused no distortion. All records were taken with the commutator brushes lifted, so that the only current in the armature coils was the equalizing current.

The first record taken was of the equalizing currents in two diametrically opposite armature coils with all four field coils normally excited in series. The only unbalance in the magnetic circuit was due to the air gaps under the two lower poles being slightly less than those under the two upper poles. The record of the coil currents resulting from this unbalance is shown in Fig. 1. It is seen that the equalizing connections paralleling these two coils are sufficiently low in resistance

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

that the two coils carry at each instant, exactly the same current. Although it is not shown on the oscillogram, the currents in these two coils are in opposite directions. Thus it is equivalent to a circulating current between the two coils set up by the difference of their generated voltages. Their generated voltages result not only from the cutting of flux, but also from their mutual interlinkages with other coils which are carrying current. An inspection of Fig. 2 will show that from symmetry, the equalizing current variation in any armature coil should repeat, except for a reversal of sign, twice each revolution. The fact that this condition was not obtained in Fig. 1 is explained by a dissymmetry of rotor iron. That is, the air-gap under any main field pole varies slightly as the armature is rotated.

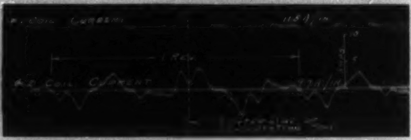

Fig. 1—Equalizing Current in Two Diametrically Opposite Armature Coils. (See Fig. 2)

Using the experimentally determined curve of equalizing current given in Fig. 1, an analysis will be made to show how equalizing currents correct the unbalance causing them to flow.

To eliminate the effect of dissymmetry of rotor iron, the curve of equalizing current is averaged so as to repeat, with signs changed, every two pole-pitches, and is plotted as the solid line curve of Fig. 3. It can be assumed that this is the current variation in the conductors of the top coil side of slot *A*, for after this assumption is made, the relation between the direction of the current and the direction of the resulting m.m.f. can be determined by the substitution of a known magnetic unbalance with a known polarity such as the partial excitation of a single field coil. From an inspection of Fig. 3, it is obvious that the bottom coil side of slot *A* is, at any instant, carrying a current of the same magnitude, but opposite in direction to that carried by the upper coil side just one pole-pitch earlier. Thus it is possible at once to plot the dotted curve of Fig. 3 showing the variation of conductor current in the lower side of slot *A*. The average conductor current in a slot multiplied by the number of conductors gives the total slot current as shown in Fig. 4.

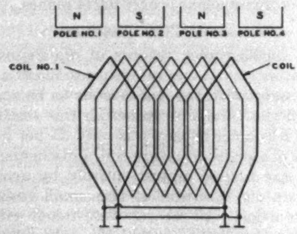

Fig. 2—Development of Armature Winding Showing Coils Nos. 1 and 2

For simplicity, only one pair of equalizing connections is shown

Since the value of current in a slot is dependent only upon the position of the slot relative to the main field poles, the curve of slot current will just as well represent a current sheet around the armature, fixed in space and therefore setting up a constant magnetic field relative to the main field poles. The m.m.f. resulting from this current sheet is represented by the heavy line curve of Fig. 4, which is simply the integral of the slot current curve. The scale of the m.m.f. curve was determined from the current scale and the number of slots per unit length of armature periphery, and is plotted in per cent of the normal excitation of a single main field pole.

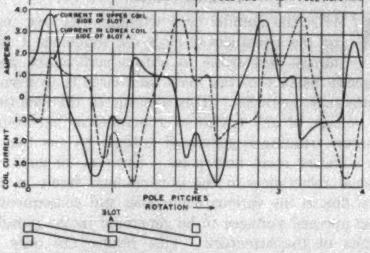

Fig. 3—Conductor Current in Upper and Lower Coil Side of Slot *A* Plotted Against the Position of Slot *A* Relative to the Main Field Poles

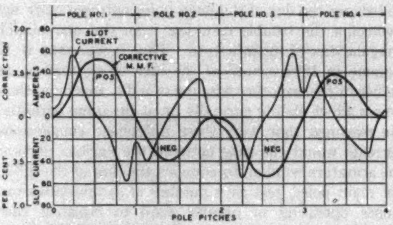

Fig. 4—Slot Current and Corrective M.M.F.

Referring to Fig. 5, it can be seen that the correction is proper. The corrective m.m.f. is in such a direction as to aid the flux of poles Nos. 3 and 4 and to oppose the flux of poles Nos. 1 and 2. An oscillogram of generated coil voltage showed that the equalization was practically perfect.

In a way the four-pole machine is unique. For instance, it has already been observed that the curve of equalizing current in an armature coil must repeat with the signs changed every two pole-pitches or twice each revolution. From the foregoing analysis it follows that the curve of corrective m.m.f. must also repeat twice each revolution. That is, the correction of two opposite poles must be equal and opposite. This is not at all surprising, for the unbalance must occur between opposite poles before it is effective in setting up equalizing currents. The unbalance of adjacent poles may be very great, and yet if opposite poles are equal in strength, the flux in all four poles will be equal.

The oscillogram of Fig. 6 was taken with only pole No. 2 of the machine excited, and shows records of generated coil voltage and coil current of one armature coil. It is interesting to notice the completeness of the equalization. Although only one field coil was excited, the flux in all poles is of the same amount and in the proper direction. The excitation of the pole was about 30 per cent normal. An analysis of the coil current curve showed that the equalization was accomplished by a corrective m.m.f. of 15 per cent sending flux from pole No. 4 into the armature, and a corrective m.m.f. of 15 per cent opposing the original 30 per cent excitation of pole No. 2. The correction under poles Nos. 1 and 3 was practically nil.

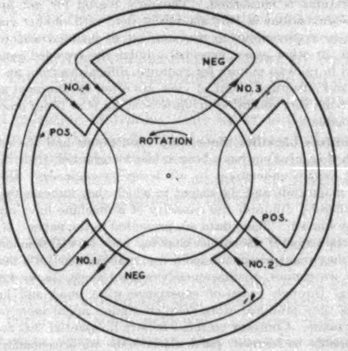

Fig. 5—Schematic Diagram of Magnetic Circuit Showing Normal Flux Distribution

A similar record taken on the machine with poles Nos. 1 and 2 excited to 30 per cent normal value is shown in Fig. 7. In this case the equalization required a corrective m.m.f. under each of the poles. Under pole No. 1 it was 15 per cent from pole to armature; under pole No. 2 it was 15 per cent from armature to pole; under pole No. 3 it was 15 per cent from armature to pole; and under pole No. 4 it was 15 per cent from pole to armature. With two poles originally excited, the final flux density under the poles was just twice that obtained from the original excitation of one pole.

It might be said that the analysis set forth in this paper was started almost with the answer. No attempt was made to solve the very difficult problem of theoretically determining the equalizing current set up in the armature coils by a certain unbalance in the main field circuit. The main purpose of the writer was to show how the oscillograph might be used in a study of the behavior of equalizing connections.

The process by which equalizing currents are set up in an armature is fairly well known, but the complications arising from the mutual inductance between armature coils and the existence of many overlapping circuits are so great that an accurate analytical solution of the problem seems practically impossible. It is firmly believed that a complete analysis similar to the one given in this paper, but one made on a machine with a large number of poles, would furnish enough empirical data that an accurate quantitative analytical solution would not be necessary. The number and size of the equalizing connections could be changed and if necessary, the analysis could be extended to two or three sizes or types of machines, so that the results could be interpolated for intermediate points. If later it does appear desirable to make a complete theoretical analysis of the problem, the analyzed data obtained on the actual machines would be of great value as a check on proposed theories.

Discussion

R. E. Hellmund: Such a study as that covered by Mr. Baker relating to equalizing connections on commutating machinery is very desirable because, in spite of the fact that equalizing connections have been used for a great many years, the design engineer is still continuously confronted with questions relating to their application. While equalizing connections are of course always used with parallel-wound armatures, it is frequently difficult to decide to what extent they should be used and which of the various possible arrangements at the front or rear end of the armature leads to the most economical and reliable design.

Equalizing connections fulfil two functions: that of equalizing the fields of the various poles, as covered in Mr. Baker's paper, and, in addition, a function which is not as generally recognized. This second function relates to the transfer of current from one brush arm to another of the same polarity whenever the brush, on account of mechanical inaccuracies of the commutator, temporarily jumps and fails to make contact with the commutator. This is exceedingly important in practise because, as is probably recognized by all designers of large and high-speed commutating machinery, by far the largest part of their commutating difficulties are due to mechanical inaccuracies or so-called "high bars" of the commutator. It can readily be seen that when a brush leaves a commutator bar which is directly connected by an equalizing connection to another bar of the same polarity, the current can temporarily transfer through this equalizing connection to such other bar, and unless such transfer is opposed by high self-induction of the equalizing connection, no sparking will result at the brush leaving the commutator. If, on the other hand, there is no equalizing connection to such bar, the transfer of current has to take place through a part of the armature winding. This may apply either if the cross-connections are at the rear of the armature or at the commutator end but limited to a small number of bars. Any transfer of current taking place would then be opposed by the self-inductive effect of part of the armature winding, and the self-inductive voltage thus obtained is likely to maintain a spark between the commutator and the jumping brush. It is for this reason that best results are usually obtained with 100 per cent cross-connections at the commutator, or, still better, with the so-called "involute winding."

Unfortunately the merits of the more expensive and often difficult arrangements for cross-connections cannot be readily determined from ordinary comparative tests because both functions previously mentioned are affected by inaccuracies of manufacture which are difficult to duplicate. The function relating to the equalizing of the field is affected by inaccuracies in various portions of the air-gap which cannot be measured easily. The function relating to the transfer of brush current is affected by inaccuracies of the commutator as small as one ten-thousandth of an inch, which are also difficult to determine, and which moreover are subject to change during the tests due to different expansion and contraction with changes in temperature. It is for this reason that the only hope of clarifying the subject rests in systematic studies in which a number of variables is eliminated, such as carried on by Mr. Baker.

Thomas T. Hambleton: The introduction to the paper recognizes the fact that armature equalizer connections are a matter of ancient history and that their action is thoroughly understood by all designers.

It seems appropriate from the historical standpoint to mention a coincidence which is not infrequently encountered in the development of an art or science. It occasionally happens that two or more individuals independently and concurrently arrive at the same solution of a problem. Such a coincidence appears to have occurred in connection with armature equalization. The old records of the General Electric Company contain drawings made in 1895 showing involute formed equalizers mounted at the end of commutators and connected directly to the segments, thus providing complete equalization at the most advantageous point as regards another function of the equalizers which Mr. Baker has not mentioned.

Besides providing paths for the circulation of magnetizing currents which equalize field fluxes, equalizer connections also carry between parallel brush groups interchange currents caused by irregularities in the mechanical condition or the contact surface condition of the commutator.

An equalizer located at the commutator end of the machine has minimum impedance for these currents; when the equalizer is located at the back end of the armature these currents must at least twice traverse the armature slots in addition to the equalizer, thereby encountering the high impedance of the iron-embedded conductors.

It is evident that a type of equalization considered perfect today was used on some very early machines.

R. E. Hellmund: I agree with Mr. Hambleton in his statement that 100 per cent cross-connections at the front end are desirable as far as obtaining the best result from the equalizing connections is concerned. The only reason for not applying cross-connections in this manner is that with smaller machines and less severe conditions they may not be justified economically. Again, in other cases, especially under the crowded conditions found in railway motors for instance, difficulties from an insulation and structural point of view are often encountered and the use of the very desirable involute winding is at times practically impossible.

Thomas Linville: Equalizing connections and the currents which flow in them have been taken for granted, their function being clearly understood by all designing engineers. However, their magnitude and the extent to which they increase the losses and thereby diminish the capacity of a machine have not been widely known. These data are presented in the paper. It seems that the value of the connections has been so well demonstrated that they must be considered a fundamental part of a machine. Since we cannot divorce ourselves from them, as we know in general through years of experience what good and harmful effects they produce, more detailed studies might seem of little importance. Contrary to this I believe it essential that as much as possible be learned, particularly since we occasionally want to build a machine with purposely unbalanced magnetic fields and want to know how effectively the equalizing currents will function. Again because of the existence of these currents in commutating coils, and because the brushes always form parallel equalizing paths, it is important to know exactly how they affect commutation. Also a great deal of information concerning the action of equalizing currents in some types of a-c. machines is needed. Finally for the currents to be effective in the desired way they must be largely reactive currents. Hence, we want to know how low the resistance of the connections must be and how complete the equalization will be with a given resistance. The fact that the currents are determined practically by reactance alone is what makes their calculation difficult. Much experience, test data, and well-established convictions answer these wants but the need for still more definite data is great. Therefore, I think Mr. Baker's work is worth while.

It is encouraging to see such excellent results obtained with the oscillograph because its use is essential in making experimental studies and in proving theories. In some cases, with big machines, real difficulties are met due to stray fields, etc., causing distorted oscillograms when extreme care is not used.

Calculation of No-Load Damper Winding Loss in Synchronous Machines

BY E. I. POLLARD*

Non-member

Synopsis.—Pulsations in the air-gap induction due to the slotted stator construction produce pole-face loss. When a damper winding is present the pulsations link the damper bars producing circulating currents causing an additional loss, which is designated by the term "no-load damper winding loss." The magnitude of this loss is found to vary from practically zero to as much as eight times the pole-face loss, or to as much as half of the total no-load core loss. A method of calculating the no-load damper loss is developed based on theoretical considerations. As far as the writer is aware no theoretical work has been previously published on this subject.

DEVELOPMENT OF THE FORMULA

IN synchronous machines, the non-uniform nature of the air-gap due to the presence of alternate teeth and slots on the stator results in a non-uniform distribution of flux density at the surface of the rotor, the maxima of density being opposite the teeth and the minima opposite the slots. Flux maps of the air-gap field for a slotted stator have been published by several writers.[1,2] The relation between the actual and average densities from point to point over a tooth pitch along the air-gap, derived from flux maps, is shown by Wieseman.[1] The induction at the rotor side of the gap may be resolved into an average induction and a superimposed pulsation or ripple. The latter is the object of interest from the standpoint of damper loss. In producing the ripple, the teeth may be regarded as north poles, the flux returning to consequent or imaginary south poles occupying positions in the slots as indicated in Fig. 1.

In most machines, the damper slots are but partially closed, so that the reluctance of the opening above the slot is large compared with the reluctance of the path through the iron around the slot. The pulsation flux from a north to a south pole will, therefore, link the damper slots which interrupt the otherwise smooth surface of the pole-face. Any two bars form a closed circuit linking the enclosed pulsation flux. The position of maximum interlinkage occurs when the central point between the bars is opposite the center of either a stator tooth or slot. The frequency of the flux pulsation with respect to a point on the rotor surface is equal to the number of stator slots per pair of poles multiplied by fundamental or line frequency. Therefore, the rate of change of interlinkage of pulsation flux with a pair of damper bars is quite large, inducing a considerable voltage around the closed circuit formed by the two bars. Assuming that the circuit is open, it is possible to calculate the voltage induced around the circuit, the total inductive reactance, resistance, and impedance of the circuit, and from these calculate the current which flows when the circuit is closed. However, since the effect of the resistance upon the impedance is quite small, it is preferable to assume that the reactance and impedance are equal and calculate the current directly on the basis that the magnitude of the current is determined by zero interlinkage of flux with the circuit. In other words, the flux produced by the flow of current is equal to and completely cancels the flux enclosed by the circuit before it is closed. This damping action leads to the suggestion that the circuit formed by each pair of adjacent damper bars be defined as a "damping circuit." On this basis each damper bar becomes a part of two damping circuits, the return paths of these circuits being the two bars adjacent to the one considered, as indicated in Fig. 1. The total current in the bar is, therefore, the resultant of the currents flowing in the two damping circuits of which the bar is a part. The current in the damping circuit is obtained by use of the relation:

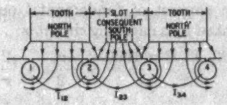

FIG. 1

damping circuit m.m.f.

$$= \frac{\text{total enclosed pulsation flux}}{3.19 \times \text{total permeance of damping circuit}}$$

or

$$I_c = \Phi/\sqrt{2}\ 3.19\ \lambda \qquad (1)$$

The total enclosed pulsation flux must be construed to include the mutual flux set up in the damping circuit considered by currents in all other damping circuits, as well as the flux set up in it by the non-uniform air-gap permeance. That is:

$$\Phi = \Phi_p + \Phi_m \qquad (2)$$

The total permeance of the damping circuit may be separated into the air-gap permeance and the permeance of the slots forming the circuit:

$$\lambda = \lambda_g + 2\ \lambda_s \qquad (3)$$

---

1. For references see Bibliography.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

Let K_p represent the difference between the maximum and the minimum values of air-gap induction measured at the rotor side of the gap opposite the centers of a tooth and of a slot respectively, and expressed as a fraction of the maximum induction. Then the average amplitude of the pulsation component of induction is

$$\frac{K_p\, K_g\, B \times 1000}{2}$$

The factor 1000 is required since B is expressed in kilolines per square inch.

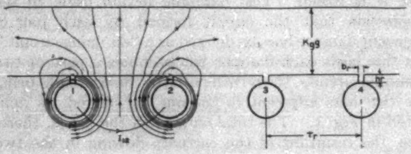

FIG. 2

The dissimilarity between the positive and negative halves of the tooth pulsation field form reveals the presence of a prominent second harmonic in addition to the fundamental, both of which will be considered. Accuracy does not seem to warrant extension of the Fourier's analysis beyond the second harmonic. Denoting the amplitude of the fundamental of field form as K_{w1} × average amplitude of induction pulsation, then the maximum amount of fundamental pulsation flux that can be linked by a damping circuit is:

$$\Phi_p = \frac{K_{w1}\, K_g\, K_p\, B \times 1000}{2} \times \frac{\tau_s}{2} \times \frac{2}{\pi} \times \sin \phi/2$$

or

$$\Phi_p = 159\, \tau_s\, B\, K_{w1}\, K_p\, K_g \sin \phi/2 \qquad (4)$$

The term $\sin \phi/2$ is the chord factor of the damping circuit, ϕ being the "throw" of the damping circuit, or damper bar pitch, expressed in electrical degrees. Since τ_s = 360 electrical degrees for the pulsation,

$$\phi = \tau_r/\tau_s \times 360^\circ$$

The angle ϕ is also the time phase angle between the currents in adjacent damping circuits.

Referring to the circuit consisting of bars numbered 1 and 2 in Fig. 2 whose current I_{12} at some instant is outward in bar 1 and inward in bar 2. The various paths taken by the flux produced by I_{12} are indicated by arrowed lines. The flux crossing the gap may be regarded as returning through some other damping circuit in which the current is in phase opposition to I_{12}. The net effect of the m.m.f. of the current I_{12} on the permeance of the damping circuit consisting of bars 3 and 4 is practically zero, and does not alter the amount of flux linked by bars 3 and 4. However, the m.m.f. of the current I_{12} acting on the slot permeance of bar 2 produces flux linked by the circuit consisting of bars 2 and 3, which is the flux Φ_m mentioned above. The magnitude of Φ_m is:

$$\Phi_m = 3.19 \sqrt{2}\, I_c \cos \phi \times 2\, \lambda_s \qquad (5)$$

Substituting equations (2), (3), (4), and (5) in equation (1) gives

$$I_c = \frac{159\, \tau_s\, B\, K_{w1}\, K_p\, K_g \sin \phi/2 + 2 \times 3.19 \sqrt{2}\, \lambda_s\, I_c \cos \phi}{3.19 \sqrt{2}\, (\lambda_g + 2\, \lambda_s)}$$

Solving for I_c:

$$I_c = \frac{35.3\, \tau_s\, B\, K_{w1}\, K_p\, K_g \sin \phi/2}{\lambda_g + 2\, \lambda_s\, (1 - \cos \phi)} \qquad (6)$$

The resultant current in the bar is the vector difference of the two currents I_c in the two damping circuits of which the bar is a part, displaced in time by the angle ϕ. Hence

$$I_r = I_c \sqrt{2\, (1 - \cos \phi)}$$

or

$$I_r = \frac{35.3\, \tau_s\, B\, K_{w1}\, K_p\, K_g \sin \phi/2 \times \sqrt{2\, (1 - \cos \phi)}}{\lambda_g + 2\, \lambda_s\, (1 - \cos \phi)}$$

Since

$$\sin \phi/2 = \sqrt{\frac{1 - \cos \phi}{2}},$$

$$I_r = \frac{35.3\, \tau_s\, B\, K_{w1}\, K_p\, K_g\, (1 - \cos \phi)}{\lambda_g + 2\, \lambda_s\, (1 - \cos \phi)} \qquad (7)$$

The effective bar resistance is

$$K_f\, R = \frac{\rho\, K_f\, l}{10^6\, a} \qquad (8)$$

Assuming that all damping circuits are physically identical, since n is the total number of bars on the machine, the total loss resulting from the fundamental of the pulsation field form is:

$$P_1 = n\, K_{f1}\, R_1\, I_{r1}^2 \times 10^{-3} \qquad (9)$$

The principal error introduced by the above assumption is that the damping circuits consisting of the outer bars in the pole tips of adjacent main poles are quite dissimilar from the remaining circuits so that the loss in the outer bars is actually different from the assumed value. Correction will not be made for this effect in the present paper.

Substituting equations (7) and (8) in (9) gives:

$$P_1 = \frac{1.246\, n\, l\, \rho\, K_{f1}}{10^6\, a} \left[\frac{\tau_s\, B\, K_{w1}\, K_p\, K_g\, (1 - \cos \phi)}{\lambda_g + 2\, \lambda_s\, (1 - \cos \phi)} \right]^2.$$

The same reasoning applies throughout to the second harmonic of pulsation field form, giving a similar formula. The total loss for both fundamental and second harmonic is:

$$P = \frac{1.246\, n\, l\, \rho}{10^6\, a}\, (\tau_s\, B\, K_p\, K_g)^2$$

$$\times \left[K_{f1} \left(\frac{K_{w1} (1 - \cos \phi)}{\lambda_g + 2 \lambda_s (1 - \cos \phi)} \right)^2 + K_{f2} \left(\frac{K_{w2} (1 - \cos 2 \phi)}{\lambda_g + 2 \lambda_s (1 - \cos 2 \phi)} \right)^2 \right] \qquad (10)$$

EVALUATION OF UNDETERMINED FACTORS IN EQUATION (10)

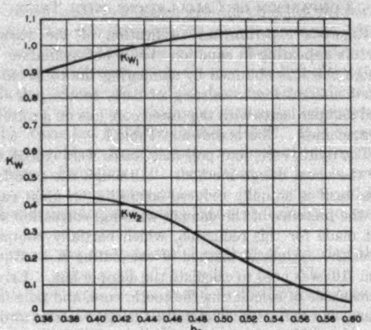

FIG. 3

1. *The effect of proportions of air-gap and stator slot—K_p.* The length of air-gap and stator slot width determine the factor K_p. The relation between these quantities is given by Mr. F. W. Carter[2] as follows:

$$K_p = 1 - \frac{1}{\sqrt{1 - (b_s/2\,g)^2}}$$

This has been checked graphically by Mr. R. W. Wieseman.[1]

2. *The effect of proportions of stator slot and tooth—K_{w1} and K_{w2}.* From flux maps of the air-gap field in the region of a stator slot, it is evident that the field is practically uniform over a sizeable portion of the tooth.[1] This, of course, results in a flat-topped shape for that portion of the tooth pulsation field form, which is opposite the stator tooth. Obviously, the effect of increasing the width of the tooth is to widen the flat-topped portion of the field form. Thus the relative widths of slot and tooth have a very considerable effect upon the field form and consequently upon the magnitudes of the harmonics into which the field form is resolved.

Several other flux maps similar to those of Mr. Wieseman show that the field form is also affected to some extent by the length of air-gap. Other proportions remaining unchanged, an increase in the air-gap shortens the flat-topped portion of the field form. However, within the range of proportions usually found in salient pole synchronous machines, this effect is relatively much less important that that of the proportions of slot and tooth, so that the magnitudes of the harmonics of the field form may be assumed to be functions only of the ratio of stator slot width to tooth pitch, b_s/τ_s. The values of K_{w1} and K_{w2} are plotted against b_s/τ_s in Fig. 3, and were obtained from Fourier's analyses of pulsation field forms.

3. *Calculation of the permeances λ_g and λ_s.* The slot permeance λ_s may be regarded as the sum of three component permeances, the permeance of that part of the slot occupied by the bar, λ_b, the permeance of the slot above the bar, λ_a, and a tooth-tip permeance, λ_t, representing the flux fringing out into the air-gap. Then

$$\lambda_s = \lambda_a + \lambda_b + \lambda_t.$$

For uniform current density in the bar, $\lambda_b = 0.75$, approximately.[3] Since the frequency of the damping currents is quite high, the current density will not be uniform but will be high at the top of the bar, decreasing toward the bottom. Thus for the same total current in the bar the flux crossing it will be reduced since h_b is in effect reduced, and λ_b will be less than for uniform current distribution. Since the increase in resistance K_f is a measure of this skin effect, the value of λ_b will be reduced, approximately, by K_f. Since λ_b is a small portion of λ, this rough approximation is acceptable. Then, for round or square bars

$$\lambda_b = \frac{0.75}{K_f}$$

The magnitude of the slot permeance above the bar is:

$$\lambda_a = \frac{h_r}{b_r}$$

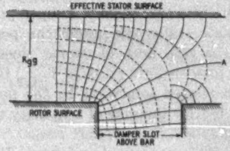

FIG. 4—MAP OF FIELD PRODUCED BY CURRENT FLOWING IN BAR IN SLOT SHOWN AND RETURNING IN ADJACENT BAR AT THE LEFT FOR $\frac{b\,r}{K_g\,g} = 1.0$

The values of λ_g and λ_t are obtained from a series of flux maps similar to Fig. 4. The flux line marked *A* in Fig. 4 is the dividing line between the gap permeance λ_g and the tooth-tip permeance λ_t. Since the field of Fig. 4 is practically uniform a short distance to the left of the damper slot, it is evident that for a given effective gap, λ_t is independent of τ_r.

Maps similar to Fig. 4 show that λ_t is a function of $b_r/K_g\,g$. Calculated from these maps, the magnitude of λ_t is submitted in curve form in Fig. 5. The set of maps for various values of $b_r/K_g\,g$ shows that λ_g is independent of $b_r/K_g\,g$ while Fig. 4 shows that λ_g does depend upon $\tau_r/K_g g$ and in fact may be taken as approximately equal to $\tau_r/K_g g$.

$$\lambda_g = \tau_r/K_g\,g.$$

By calculating λ_g in this manner, the non-uniformity of the air-gap permeance due to the stator teeth and slots is neglected. More complete analysis would show that for a given combination of slot and gap dimensions and bar pitch, λ_g is equal to $\tau_r/K_g g$ plus a superimposed periodic function of time. Referring to Fig. 1, λ_g for bars 1 and 2 is larger than for bars 2 and 3, so that the current I_{12} is less than I_{23}. But since we are interested chiefly in the resultant current in bar 2, which is the same as if the average value of λ_g had been used for both circuits, the final result is unaffected. In Fig. 1 by omitting bars 1 and 3 the condition of $\tau_r/\tau_s = 1.0$ is obtained. In this case, since a damper pitch extends over a complete stator slot pitch, the periodic component of λ_g is zero and, of course, does not affect results. For intermediate ratios of τ_r/τ_s, the resultant bar current is altered somewhat by the periodic component of λ_g, but for the sake of simplicity this will not be considered.

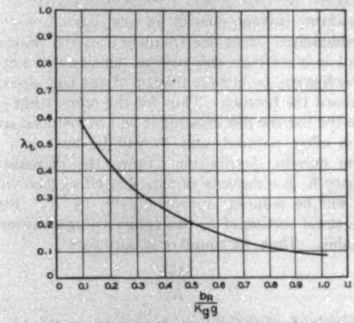

FIG. 5—DAMPER TOOTH-TIP PERMEANCE λ_t

4. *Calculation of increase of resistance*, K_f. Various investigators[4] have calculated the ratio of the a-c. to d-c. loss in a solid conductor placed in an open rectangular slot, based on the assumption that the flux produced by current in the conductor crosses the slot in straight parallel lines. Since partially closed rather than open damper slots are almost universally used in modern synchronous machinery the effect on K_f of partially closing the slot is to increase the ratio of a-c. to d-c. loss, K_f. In the absence of a rigorous treatment of this subject, K_f may be calculated by the open-slot formula, remembering that it is optimistic.

COMPARISON OF CALCULATIONS WITH TESTS

Rigorous experimental verification of the various factors appearing in equation (**10**) is not available. A rough check is obtained by comparing the total calculated no-load loss consisting of core, tooth, pole-face and damper losses with the tested core loss on a number of machines. This is shown in Table I.

The tooth, core, and pole-face losses were calculated by the usual design methods. Although the pole-face loss itself is actually reduced somewhat in most cases by the presence of the damper winding, correction was not made for this reduction, which partially compensates the optimistic method of calculating K_f. Equation (**10**) was used to calculate the damper loss. Errors in methods of calculating the tooth, core, and pole-face losses, and variations in manufacturing processes and in the materials themselves tend to prevent consistency of the results of such a check. In choosing the examples for Table I, machines having relatively large pole-face loss were preferred in order to minimize as much as possible the effect of errors in the calculation of the core and tooth losses These machines were all designed and built before the factors controlling damper loss were known. As a result, some very unfavorable combinations were accidentally used. Example No. 12 is outstanding in this respect, the damper loss being over eight times the pole-face loss. The designer of this machine estimated the total core loss to be about thirty kilowatts, and the test results could not be explained. These remarks also apply to examples Nos. 6, 7, and 10. In each case the high damper loss was due to a combination of unfavorable conditions: τ_r/τ_s = about 0.5, bar resistance is high and the total number of bars is large. In examples Nos. 1, 3, 8, 9,

TABLE I

	Poles	Kva.	Calculated core and tooth loss	Calculated pole face loss	Calculated damper loss	Total calculated loss	Test loss
1	8	3,000	17.1	5.1	0.38	22.6	18
2	8	2,920	17.3	5.3	4.5	27.1	31
3	14	5,270	28.3	10.0	0.40	38.7	40
4	16	692	3.32	1.86	3.04	8.22	7.5
5	24	3,750	30.5	15.8	13.5	59.8	57.5
6	26	1,500	7.8	5.4	12.7	25.9	26.0
7	26	1,500	6.39	1.9	3.74	12.03	15
8	40	1,125	8.8	5.5	2.4	16.7	17.7
9	48	1,750	10.5	3.5	0.33	14.3	13.6
10	56	1,250	14.6	9.8	17.2	41.6	36.7
11	58	2,000	11.9	9.4	0.49	21.8	23.6
12	88	5,000	24.1	3.3	27.6	55.0	54.0

and 11, favorable combinations were accidentally chosen when these machines were designed, and the test core losses were considered unaccountably low. Table I emphasizes the extremely variable nature of the no-load damper loss, and indicates the value of some method by which the magnitude of this loss may be estimated.

CONCLUSIONS

Several ways by which the damper loss may be minimized are suggested by equation (**10**). In general, any change made in a design with the object of reducing pole-face loss also decreases the magnitude of the damper loss, unless the ratio τ_r/τ_s is thereby made less favorable. However, such changes usually affect the fundamental proportions of the machine; air-gap length, number of slots, etc., which are frequently determined not by losses but by other characteristics. It is, therefore, preferable to look for better methods of controlling this loss. Equation (**10**) shows that the loss is proportional to the number of bars on the machine and to the bar resistance, suggesting that it is desirable to keep these quantities small.

Perhaps the most powerful method of reducing the loss is by adjustment of the ratio τ_r/τ_s. When $\tau_r/\tau_s = 1.0$ the terms $1 - \cos\phi$ and $1 - \cos 2\phi$ in equation (**10**) are equal to zero, causing the damper loss to vanish. The loss is quite small down to $\tau_r/\tau_s = 0.85$. However, when $\tau_r/\tau_s =$ about 0.5 the loss is usually excessive, and this condition should be avoided if possible. In cases where a low value of telephone interference factor is imperative, the use of nearly equal rotor and stator slot pitches should be applied with caution since some unpublished work of Mr. S. L. Henderson* indicates that this condition frequently results in a higher telephone interference factor than where τ_r/τ_s is about 0.65. With this exception, this method of reducing damper loss may be applied without impairing other characteristics.

Increasing the rotor slot pitch increases λ_g, and assists in reducing loss, being a secondary effect accompanying reduction in the number of bars. Increasing the term λ_t by deeply embedding the damper bars in the pole-face also assists in reducing loss.

In conclusion the author wishes to express his indebtedness for helpful criticism and suggestions to Messrs. J. F. Calvert, L. A. Kilgore and S. Beckwith,* with whom he conferred from time to time during his investigation of this problem, and to Messrs. M. W. Smith and C. M. Laffoon* for criticism of the manuscript.

NOMENCLATURE

a = area of damper bar (sq. in.)
B = average air-gap induction (kilolines per sq. in.)
h_b = depth of damper bar (in.)
h_r = depth of rotor slot tip above bar
f = stator tooth frequency = number of slots per pair of poles × machine frequency
g = air-gap length (in.)
I_c = current in damping circuit (amperes)
I_r = resultant current in damper bar
K_g = air-gap coefficient
K_f = ratio of a-c. to d-c. loss in damper bar
K_p = double amplitude of air-gap induction pulsation in terms of maximum induction, at rotor surface
K_w = magnitude of field form harmonic in terms of K_p (Fig. 3)
l = length of damper bar (in.)
n = total number of damper bars on machine
P = no-load damper loss (kw.)
τ_r = rotor slot pitch (in.)
τ_s = stator slot pitch (in.)
R = d-c. resistance of damper bar (ohms)
b_s = stator slot width (in.)
b_r = width of rotor slot opening above bar (in.)
b_b = width of damper bar (in.)
λ_a = permeance of rotor slot above bar
λ_b = permeance of that portion of the rotor slot which is occupied by the bar
λ_g = air-gap portion of damping circuit permeance
λ_t = rotor tooth-tip permeance (Fig. 5)
Φ_p = maximum amount of pulsation flux due to air-gap permeance variation, which is linked by a damping circuit
Φ_m = mutual pulsation flux linked by a damping circuit due to currents in other circuits
ϕ = phase angle between currents in adjacent damping circuits $= \tau_r/\tau_s \times 360$ deg.
ρ = resistivity of bar material (microhms per cu. in.)

Subscripts 1 and 2 refer to fundamental and second harmonic respectively.

Discussion

C. C. Shutt: Mr. Pollard's paper gives the designer of synchronous machines another useful tool for the predetermination of their performance. The test results of example 12, Table I, demonstrated clearly the necessity for the investigation which he undertook. The particular machine of example 12 in Table I happened to be a motor. The damper bar material had a resistance 15 times that of copper and the slot ratio was conclusive to high damper winding losses.

In synchronous motor design the use of relatively high resistance damper bars is becoming increasingly common as a means of reducing the starting kva. and improving the starting power factor. From equation (**10**) of the paper, it is apparent that the loss increases directly with the effective resistance of the damper bars. This makes it particularly necessary to check the design of synchronous motors from the standpoint of ratio of rotor to stator slot pitches.

---

*All of the Power Engg. Dept., Westinghouse Elec. & Mfg. Co.

On a new line of synchronous machines, which was recently developed, this feature was checked before making the drawings. The number of stator and rotor slots per pole was determined by other considerations. The pitch of the slots in the pole punchings was set so as to avoid improper ratios from the standpoint of no-load damper loss. This necessitated unequal pitches of the pole face slots in several of the poles. The tests of no-load loss on this line of machine compare favorably with the calculated values.

R. E. Hellmund: The practical importance of damper winding losses has, of course, been appreciated by designers for some time. I recall cases where what seemed to be a rather insignificant increase in the ratio of the secondary bars of a squirrel-cage motor to the number of primary slots increased the no-load losses of the motor from 50 to 100 per cent. Furthermore, it is easily seen that if the top of the teeth of the rotor are smaller than the slot openings of the stator, it will result either in large flux fluctuations in the rotor teeth and consequent core losses, or else in large losses from the corrective current in the squirrel-cage bars. As a matter of fact, in the example of the induction motor previously referred to, the losses caused by the flux changes in the teeth, if allowed to exist by removing the winding, were of about the same order as the losses caused by the corrective current with the winding in place. Although there was previously a qualitative appreciation of the factors touched upon in Mr. Pollard's paper, his quantitative analysis of the problem is of great value.

As in most other cases of design, there are in this case several reasons why the use of the proportions giving ideal results in one respect, such as the minimum damper winding losses covered in the paper, cannot be applied. This in turn makes it desirable to determine just how great a departure from the ideal is advisable in order to favor other factors of importance. A large number of secondary bars, for instance, is usually desirable on account of the favorable effect upon the power factor and other performance features of induction motors. Again, it is pointed out in the paper that while a slot ratio of 1:1 gives minimum damper winding losses, it is likely to lead to telephone interference. This is due to the fact that higher harmonic currents different from those calculated in Mr. Pollard's paper are set up in the primary and secondary of synchronous and induction motors for the following reason:

With a definite voltage impressed upon these motors, the various currents have to adjust themselves so as to set up fields inducing a counter e.m.f. equal and opposite to the impressed e.m.f. Inasmuch as the field forms of the machines are usually not sufficiently ideal to accomplish this with sinusoidal magnetizing current, a flow of certain higher harmonic currents is necessary. These higher harmonic currents are usually of large amplitude with a slot ratio of 1:1 or equal slot pitch, and therefore are likely to cause telephone interference. The losses caused by these harmonics and not covered in the paper are usually of no practical importance. (In the usual open-circuit, no-load test of synchronous machines, such losses are of course not present at all.) This problem can be attacked along the lines suggested in a paper which I presented before the A.I.E.E.* and an article published in the *Electrical World* of 1906 on the subject "Magnetizing Currents in Polyphase Induction Motors."

The method given by Mr. Pollard should prove an excellent guide in choosing a secondary slot pitch appreciably different from the primary without reaching the point where the secondary damper winding losses assume undesirable proportions.

Ernst Weber: The formula (1) of the paper for the total damper winding loss contains two factors kw_1 and kw_2 which are very important since they represent the relative magnitudes of the fundamental and second harmonic of the pulsation wave and are involved in equation (10) as the square. It is important, therefore, to know their values with some accuracy. The author determined kw_1 and kw_2 from flux maps taking into account the effect of the relative widths of slot and tooth upon the field form. Obviously this method can be very inaccurate.

In 1928, I published a paper on the air-gap coefficient in machines* in which I gave a mathematical expression for the pulsation curve as

$$B_p = \overline{B}_p \cdot \left(\sin \frac{x\pi}{t_s} \right)^{2n} \tag{1}$$

with

$$n = \frac{t_s - b_s}{b_s}.$$

This expression represents for the integers n, discrete wave forms of just the type desired to take care of the ratio of slot width b_s to slot pitch t_s. The mean value follows by integration as

$$(B_p)_m = \overline{B}_p \cdot \frac{1.3.5. \ldots . (2n-1)}{2.4.6. \ldots . 2n}, \tag{2}$$

and by Fourier's analysis the amplitudes of the first and second harmonics may be determined. Their ratios to $(B_p)_m$ in (2) give the amplitude factors

$$K_{w1} = \frac{4}{\pi} \cdot \frac{2.4.6. \ldots (2n)}{1.3.5. \ldots (2n-1)(2n+1)}, \quad K_{w2} = \frac{2n}{2n+2} \cdot K_{w1}. \tag{3}$$

Contrasted with those values obtained by Mr. Pollard it is to be seen that formula (3) gives lower values for kw_1 and higher ones for kw_2 than Fig. 3 of the paper; but the variation with $\frac{b_s}{t_s}$ is of the same character. This may be taken as a satisfactory check and yet may provide a means for further correction and approximation, since it is quite easy to compute even the higher harmonics.

The effect of increase of resistance of the damper loss due to alternating current has been treated with close approximation by R. Rogowski, *Archiv. f. Elektrotech.* 1913, Vol. 2, p. 81. A formula for the ratio of a-c. loss to d-c. loss is given there so that the statement regarding the absence of a rigorous treatment of this subject does not seem correct.

As to the effect of the damper slots on telephone interference may I summarize some experiences I had in 1926 when I was associated with the Siemens-Schuckert-Werke in Vienna. In an unpublished paper I proved that minimum loss and minimum interference harmonics are two nearly opposing tendencies. For slot harmonics to be a minimum the voltage wave of the generator, I could set up the condition $0.62 < \frac{t_s}{t_r} < 0.70$ and experiments as well as careful investigation of many oscillograms showed satisfactory agreement. The damper losses, however, are not at the minimum within this range of the above ratio. Although it does not make any difference whether we write $\frac{t_s}{t_r}$ or the inverse value $\frac{t_r}{t_s}$, it seems to me that generally the stator slot pitch is made smaller than the damper slot pitch and I should like to know if Mr. Pollard purposely used $t_r < t_s$.

E. I. Pollard: Mr. Weber questions the accuracy of the

No-Load Conditions of Single-Phase Induction Motors and Phase Converters, A.I.E.E. Trans., 1918, Vol. 37, p. 539.

*E. Weber, *E.T.Z.*, 1928, Vol. 49, p. 858.

curves for Kw_1 and Kw_2 in Fig. 3. As stated, these curves were calculated from flux maps which Mr. Weber states "can be very inaccurate." Concerning the accuracy of flux maps, I refer Mr. Weber to reference 1 of the bibliography. Although I am not familiar with the derivation of Mr. Weber's equations, his relatively simple solution of a complex mathematical problem indicates that various simplifying assumptions must have been made. For instance, he neglects the effect of the ratio of slot width to gap length, as I did in Fig. 3. The assumption of a considerably different ratio of bs/g would in part account for the discrepancy, although the effect is secondary importance, except in extreme cases.

The article by Von W. Rogowski referred to by Mr. Weber considers the calculation of eddy current factors for various arrangements of coils and bars in open slots, as has been done by various other investigations, notably A. B. Field, B. Hague and Gilman. But does Rogowski take into account the effect upon field distribution and eddy factor of partially closing the slot above the bar? He does not consider the case of the round bar.

In general the rotor slot pitch is smaller than the stator slot pitch, except possibly in the case of small low-voltage machines. This is because a large number of bars is desirable from the standpoint of reduced rotor reactance and better power factor for induction motor performance of synchronous motors as pointed out by Mr. Hellmund. Also, if a smaller number of larger bars were used, they would occupy a greater depth in the pole head and pole tips, requiring a deeper pole head and resulting in increased pole tip leakage.

Sine-Wave Generators

Cylindrical Rotor Winding Connections and Analysis of Rotor M.M.F. Waves

BY LLOYD P. SHILDNECK*
Associate, A.I.E.E.

Synopsis.—*This paper describes and compares various types of double layer rotor winding connections for non-salient pole machines, with a particular application to sine-wave generators. Design coefficients are obtained by a mathematical analysis of the derived equations for the rotor m.m.f. Five specific types of connections, the V, Y, X, U, and W types, are discussed, as well as the general case. The new types advocated are seen to be superior to the old, giving a greater output for a given maximum temperature.*

GENERAL

CERTAIN applications, as iron testing, meter testing,[1] cable testing, etc., require a sine wave of generator voltage under all load conditions. The voltage wave form of an ordinary salient-pole generator is usually very good at no load, but becomes distorted under load. To overcome this inherent defect, the round-rotor type of sine-wave generator was developed. The stator of this type is very similar to that of a salient-pole generator. For the field, however, a round punched rotor is used with a double layer winding distributed in evenly spaced slots and connected to give nearly a sine wave of m.m.f.

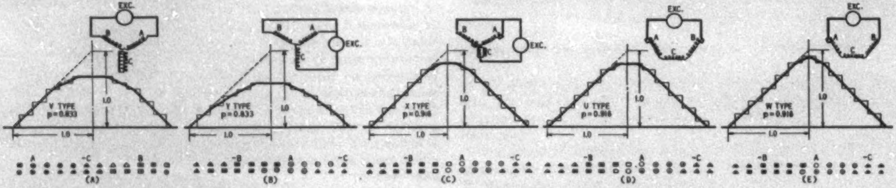

FIG. 1—ROTOR M.M.F. WAVES

Because of the equal permeances in both axes of this type, a sinusoidal air gap flux density wave is set up by any combination of sinusoidal rotor and stator m.m.f. waves. Thus a sine-wave generator has fundamentally three requirements: a round rotor, a sine wave of stator m.m.f., and a sine wave of rotor m.m.f. Of these, only the third requirement is discussed here, since the construction of the rotor is similar to that of a wound rotor induction motor, and the methods of producing a sinusoidal stator m.m.f. are well understood.[2,3,4]

The very useful, but rather tedious, *graphical* method is used to plot the flux density fields of salient-pole machines.[5] In round rotor machines, however, the permeance variable disappears, and the field m.m.f. and field flux density wave shapes are identical. Consequently, to determine the field flux density wave shape, it is but necessary to derive *analytically* the shape of the field m.m.f. wave. (The assumptions are: infinite permeability of the iron and infinite number of rotor teeth.) This method allows a direct determination for the maximum or minimum value of any coefficient, by equating the derivative to zero. The analytical method is general and applicable to all round rotor machines, but the analyses made in this paper are directly applicable only to round rotor machines with double-layer rotor coil windings. This includes the synchronous-induction motor and the sine-wave generator, but not the turbine generator.

DESCRIPTION OF TYPES OF ROTOR WINDING CONNECTIONS

A study of the two types of connections used heretofore (V and Y) revealed certain inherent undesirable features. Three new types (X, U and W) were developed as a direct result of eliminating these deficiencies.

V Type. This old type is obtained by winding the rotor with an ordinary three-phase double-layer winding, and connecting phases A and B in series with the exciter, as shown in Fig. 1A. Thus only two-thirds of the coils are used to produce the field m.m.f. The remaining coils are short-circuited individually to assist in damping out the backward rotating component of single-phase armature reaction. So

$$s = 0.333$$

---

*A-C. Engineering Dept., General Electric Co., Schenectady, N. Y.

[1] For references see Bibliography.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

is the defining equation for this type, where s = the ratio of short-circuited to total coils. This type is inferior because an insufficient ratio of coils is used in the d-c. circuit.

Y Type. In the other old type, the three phases are connected to the exciter as shown in Fig. 1B. This type has good damping features (since polyphase currents can flow to damp out the backward rotating flux), but it has serious heating limitations. The third leg C, carrying full field current, has a heating four times as great as that of either leg A or B. The heating in this "bottle-neck" leg then definitely limits the output of the rotor. The Y type has another undesirable feature in that opposing currents in the top and bottom of the same slot are used to obtain the flat top of the m.m.f. wave. (See Fig. 1B.) This, of course, increases the I^2R loss.

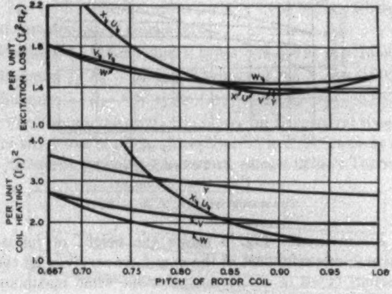

FIG. 2—FIELD EXCITATION LOSS ($I_f^2R_f$) AND HEATING (I_f^2) FOR UNIT FUNDAMENTAL

Five specific types (V, Y, X, U, W)

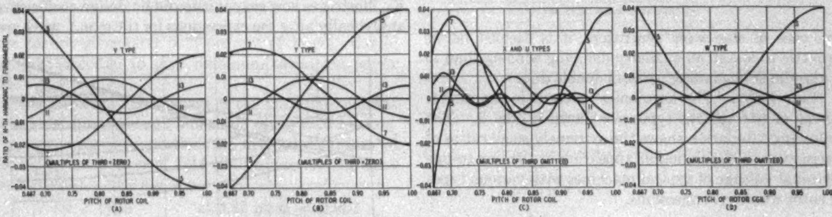

FIG. 3—HARMONICS IN ROTOR M.M.F. WAVES

Five specific types (V, Y, X, U, W)

X Type. This new type is a modification of the Y type with the following changes as shown in Fig. 1C.

Phase C is split into two parallel circuits, *thereby eliminating the bottle-neck* feature of the Y type; also the coils that carry opposing currents in the Y type are removed from the d-c. circuit, *thereby eliminating the unnecessary power loss.* From the beginning of each pole group in phase A (1-pitch) × (coils per pole) are taken and a like number from the end of each pole group in phase B, so that the two groups of short-circuited coils are adjacent. Thus

$$s = 2\,(1 - p)$$

is the defining equation for the X type, where p = rotor coil pitch.

U Type. This new type is a modification of the X type, obtained from it by joining the circuits in series, instead of in parallel, as shown in Fig. 1D. In practise this makes a very simple winding. All the coils in each pole pitch are placed in series; then those end coils which would oppose each other, are short-circuited individually. The defining equation for the U type is also

$$s = 2\,(1 - p)$$

W Type. This new type is the same as the U type, except just half as many coils are short-circuited. (See Fig. 1E.) The defining equation for this type is then

$$s = (1 - p)$$

The W type is a limiting case; any larger value of s would cause "opposing" coils, as in the Y type.

General Case. In the five specific types previously described, s is either a function of p or else is constant, enabling all the coefficients to be plotted in terms of the one variable p. In a study of the general case, however, both p and s are allowed to vary independently. Fig. 2 shows very strikingly the definite superiority of the V type (in which a series connection is used) over the Y type (in which one leg is placed in series with two paralleled legs). This superiority of the series type has also been proved by tests made by Messrs. Ganapati and Parikh.[6] Since a part series, part parallel type is inherently inferior to a series type, only the latter will be discussed in the general case. The general type of winding connections then results from placing all the coils under each pole in series, short-circuiting individually any fractional part s of them, and using any coil pitch p. It necessarily includes the V, U, and W types, but not the Y type.

It is always possible to obtain values

$$s = n\,(1 - p)$$

where n is any integer or zero. Under certain conditions of pitch, n may be fractional: $n = 1$ gives the W type; $n = 2$ gives the U or X type; all possible values of n are included in the general type.

DISCUSSION

The mathematical expressions for the m.m.f. waves of the various types of winding connections are analyzed by the method of Fourier series to obtain A_n, the value of the nth harmonic. The substitution $n = 1$ gives the fundamental (A_1) or useful part of the wave, which is proportional to the output of the rotor. The reciprocal of A_1 gives the field current (I_f) necessary to produce unit fundamental. From this value (I_f), the heating (I_f^2) and the excitation power loss ($I_f^2\ R_f$) are easily obtained. These values are listed in Table I.

Damping. The damping provided by the series types of winding connections (V, U, and W) is not very effective, because currents cannot flow in such windings so as to set up a revolving magnetic field of constant amplitude. The Y type and the X type are better fitted for damping out any backward rotating flux. However, in the case of sine-wave generators, it is deemed better practise to install an auxiliary damping winding than to make the field winding perform double duty.

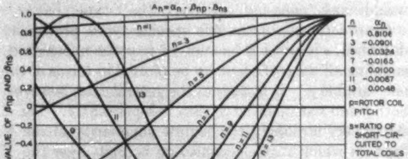

FIG. 4—MAXIMUM HEIGHT OF NTH HARMONIC (A_n)

(General type)

Wave Form. The harmonics* present in the m.m.f. waves of the various types are shown in Fig. 3. The following tabulation shows the extremely small ratios of harmonics to fundamental appearing in the line-to-line terminal voltage of typical machines with various types of rotor winding connections.

	Y type Stator pitch = 0.833 Stator slots = 72 Rotor pitch = 0.800	X or U type Stator pitch = 0.800 Stator slots = 60 Rotor pitch = 0.928	W type Stator pitch = 0.81 Stator slots = 84 Rotor pitch = 0.889
A_3/A_1	0	0	0
A_5/A_1	0	0	0.00027
A_7/A_1	0.00047	0.00003	−0.00016
A_9/A_1	0	0	0
A_{11}/A_1	0.00081	0.00026	−0.00009
A_{13}/A_1	0.00030	0.00004	−0.00014
A_{15}/A_1	0	0	0

The curves in Fig. 4 are rather unique in that they give A_n, the value of the nth harmonic, for the general type winding connections, for any value of (n) from 1 to 13, any value of (p) from 0.65 to 1.00, and any value of (s) from 0 to 0.35, *without interpolation.* This is obtained by using a double abscissa, as shown.

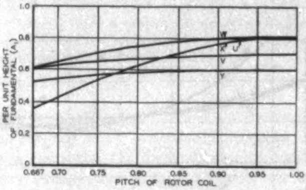

FIG. 5—HEIGHT OF FUNDAMENTAL (A_1) FOR UNIT COIL CURRENT

Five specific types (V, Y, X, U, W)

Fundamental. Fig. 5 shows the height of fundamental, or useful part of the m.m.f. wave, given by the various types of connections, for the same maximum current flowing in any part of the winding. A comparison at the pitches necessarily used to give good wave forms shows a very decided advantage in favor of the new types of connections (X, U, W).

A_1 for	Y type	at 0.82 pitch	=	0.584
A_1 "	V type	" 0.82 "	=	0.674
A_1 "	X and U type	" 0.93 "	=	0.786
A_1 "	W type	" 0.90 "	=	0.790

Thus the new types have a greater output for the same maximum temperature.

K_m and Air-Gap Ampere-Turns. The derivation of K_m illustrates how easy it is to obtain design coefficients analytically after the expressions for the m.m.f. wave are set up. K_m is simply the ratio of the maximum to the average height of the m.m.f. wave. This coefficient is very useful in determining the maximum air-gap flux density, which is proportional to the air-gap ampere-turns. The values of K_m for the general type are given in Fig. 6.

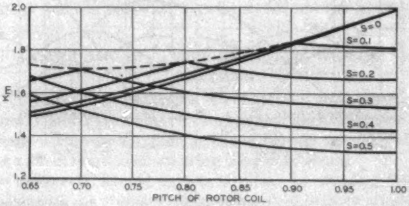

FIG. 6—$K_m = \dfrac{\text{MAXIMUM FLUX DENSITY}}{\text{AVERAGE FLUX DENSITY}}$

(General type)

---

*The third and multiples of the third are omitted in the figures for the X, U, and W types, since the Y connection of the stator eliminates them from the line-to-line terminal voltage.

Excitation Power Loss ($I_f^2 R_f$). Fig. 2 shows the power required for unit fundamental with the various specific types of connections. A comparison at the pitches to give good wave form shows that the new types require slightly less power.

$I_f^2 R_f$ for Y and V types at 0.82 pitch = 1.47
$I_f^2 R_f$ " X and U types " 0.93 " = 1.39
$I_f^2 R_f$ " W type " 0.90 " = 1.44

The minimum excitation for any type occurs where the first derivative equals zero.

Minimum $I_f^2 R_f$ for Y and V types = 1.356 at $p = 1.000$
Minimum $I_f^2 R_f$ " X and U types = 1.385 " $p = 0.902$
Minimum $I_f^2 R_f$ " W type = 1.445 " $p = 0.887$

Fig. 7 shows the excitation power for the general type. For any value of pitch, the excitation loss decreases as s is increased, reaching a minimum at $s = 0.26$. Therefore, for any given pitch p, 26 per cent of the coils should be short-circuited to give minimum excitation power loss.

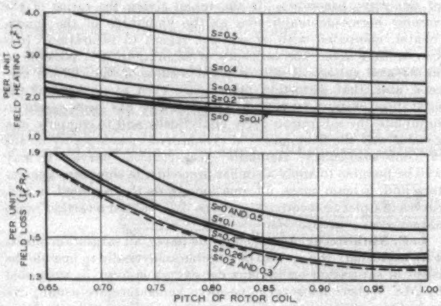

FIG. 7—FIELD HEATING (I_f^2) AND EXCITATION LOSS ($I_f^2R_f$) FOR UNIT FUNDAMENTAL

(General type)

Field Heating. The square of the maximum current in any slot gives a rough indication of the field heating. The new types of connections are decidedly superior to the old in the matter of field coil heating for the same fundamental. (See Fig. 2.)

I_f^2 for Y type at 0.82 pitch = 2.932
I_f^2 " V type " 0.82 " = 2.200
I_f^2 " X and U types " 0.93 " = 1.620
I_f^2 " W type " 0.90 " = 1.601

To obtain low coil temperature, it is seen from Fig. 7, general type, to be necessary to use a very low value of (s). The high values of pitch (and consequently, low values of s) permissible with the new types of winding account for the cool winding. Since field temperature usually limits the output of a machine, this low field heating constitutes the major superiority of the new types over the old.

CONCLUSIONS

1. Three new types of connections, X, U, and W, have been developed and shown to be superior to the old types, V and Y. By their use 15 per cent or more increase in output can be secured from the rotor without increasing the maximum temperature rise, or impairing the voltage wave shape. The Y type is decidedly inferior to the other types, because of its high maximum temperature rise.

2. The analysis made in this paper is quite general and is directly applicable to all round-rotor synchronous machines with double-layer rotor coil windings. Sine-wave generators and synchronous-induction motors are good examples of this type.

TABLE I

	A_n(For Unit I_f)	I_f(For Unit A_1)
(V)	$(8/n^2\pi^2)(\cos n\pi/6)(\sin n\pi p/2)$	$1.425/(\sin \pi p/2)$

(G-1)	$p - s$	$2 - p - s$	–	$p - s$	$1 - s$	–
(G-2)	$p - s$	$p + s$	–	$p - s$	p	–

(G-1)—General type, region I, where $1 \geqq p \geqq (1 - s)$
(G-2)—General type, region II, where $(1 - s) \geqq p \geqq s$.

3. All practical methods of making rotor coil connections have been considered, and the final results of the study listed in Table I. This comprehensive list of analytical expressions for design coefficients has been partially expanded into curve form for greater ease in making comparisons. By virtue of the information given in this table, it is now possible to choose the proper values of p and s to fit any particular case.

SYMBOLS

A_1 = maximum height of fundamental of rotor m.m.f. wave.
A_n = maximum height of nth harmonic of rotor m.m.f. wave.
I_f = field current (= coil current in series type).
K_a = ratio of fundamental armature flux to fundamental field flux for same peak values of m.m.f.
K_m = ratio of maximum to average air gap flux density.
p = rotor coil pitch.
R_f = resistance of the field winding.
s = ratio of short-circuited rotor coils to total coils.
x_1, x_2, x_3 = x-coordinates of the first, second, and third points of discontinuity of the slope of the m.m.f. wave.
y_1, y_2, y_3 = y-coordinates of the above three points.

UNIT QUANTITIES

Unit ampere-turns = 1 ampere-turn
Unit field current = 1/(turns per pole) amperes.
Unit number of coils = coils per pole.
Unit resistance = resistance of all coils in series.
Unit distance along X-axis = (pole pitch)/2.

Discussion

Ernst Weber: Although the author emphasizes in the first sentence of his paper the need for a sinusoidal wave form of the generated voltage under all load conditions, he does not mention the influence of saturation on the voltage curve in the new types of sine-wave generators. Is the table, giving the ratios of the various harmonic amplitudes to the amplitude of the fundamental, computed with or without regard to saturation? It is known that under the influence of saturation, it is possible to secure sine voltage at only a definite value of the exciting current, and, that distortion takes place even at no load, if the excitation current is varied. The attempt has been made to formulate the saturation curve analytically and to compute in a general way the field curves of synchronous machines by means of using a so-called "standard" magnetization curve.* It may well be possible to apply a similar procedure to sine-wave generators and to gain more information as to the required m.m.f. curves in order to secure sine voltage over at least a certain range of excitation current.

L. P. Shildneck: As stated in the paper, all saturation effects were neglected. It may well be possible analytically to include the effect of saturation on the flux density wave form, as suggested by Mr. Weber. However, sine-wave generators are usually required to operate over a wide range of conditions, and saturation effects must be reduced to a minimum. This is done by making the air-gap length relatively large, and the flux density in the teeth relatively low. Thus for sine-wave generators of current design it was considered unnecessary to include the effect of saturation.

Engineering Features of Three-Power Locomotives

BY F. H. BREHOB[1] and F. H. CRATON[1]
Non-member Associate, A.I.E.E.

Synopsis.—*Three-power locomotives capable of operating from an external distribution system or on internal power are in use by the New York Central and the Delaware, Lackawanna and Western Railroads. In one case the supply voltage is 600 volts direct current and in the other 3,000 volts direct current.*

The authors discuss the characteristics of this new type of locomotive and its equipment, as well as the methods of calculating the capacity and characteristics required for the service. The coordination of the diesel engine, generator, battery, and motor equipment has been carefully worked out to insure successful operation of the complete unit.

* * * * *

GENERAL

THE three-power electric locomotive operates from any of the following energy sources:

1. External power; that is, trolley or third rail.
2. Internal power from a storage battery.
3. Internal power from a storage battery and engine-driven generator connected in parallel.

Ability to operate from these power supplies gives the three-power locomotive an outstanding degree of flexibility.

Regardless of the system voltage upon which the three-power locomotive is designed to work, the general scheme of operation is the same. When using external power, the unit performs exactly as a straight electric locomotive, although the engine-generator set may be run to charge the battery. On non-electrified tracks power may be taken from the battery alone. However, if the engine is running, traction and auxiliary power are taken entirely from the engine-generator set up to its capacity above which the battery automatically assumes the excess load. On light loads, the engine-generator may run the locomotive and charge the battery at the same time.

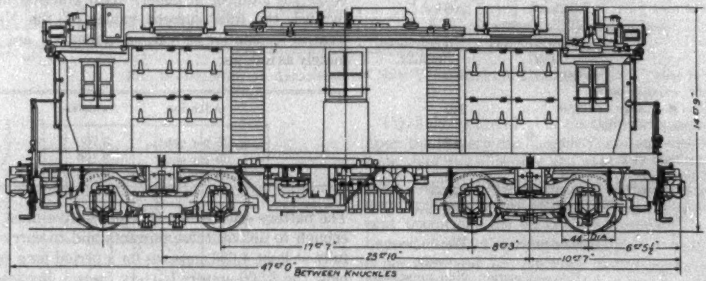

FIG. 1—OUTLINE OF NEW YORK CENTRAL LOCOMOTIVE

The New York Central Railroad tried out the first three-power locomotive in 1928, and in 1930 put 35 units into transfer and switching service on the West Side in connection with the complete elimination of steam service from Manhattan Island. The Delaware, Lackawanna & Western Railroad put two three-power locomotives into similar service in 1930 to help eliminate steam from the Bergen Tunnels with the advent of electrified suburban service from Hoboken.

Fig. 1 shows outline dimensions of the New York Central locomotive and Fig. 2 the location of apparatus in the cab. The Delaware, Lackawanna & Western locomotive is of similar mechanical and electrical design. Table I gives the pertinent data on the two locomotives and shows wherein they differ, due largely to the difference in voltages.

GENERAL REQUIREMENTS FOR INTERNAL POWER PLANT

The average power required for switching service is small while the peak demands are relatively large. The theory upon which the internal power operation of the three-power locomotive is based is that the battery will provide the excess power required for the peak demands, allowing the engine size to be cut to a minimum. Extensive tests on internal power were run in 1928 on the first New York Central three-power locomotive to determine the actual extent of these power

requirements in heavy switching service. The average for the maximum observed day for three-shift service was approximately 500 kw-hr. per eight-hour shift, or 62.5 kilowatts average load. The average work for 65 shifts of 3-shift service was 447 kw-hr. per shift. Frequently peak loads of 800 kilowatts were recorded, or more than twelve times the maximum observed average load per eight-hour shift.

For long battery life and reasonable maintenance the battery discharge should be limited to 125 per cent of the total capacity at the six-hour rate for each twenty-four hours the locomotive is operating in three-shift service. To limit the battery discharge to this value successfully, it is essential that the correct generator characteristic be used. This characteristic should be high enough and of the proper shape to insure that the engine carries the entire load up to the engine-generator capacity, but not high enough to allow the battery to recharge so rapidly that the engine must be shut down frequently to prevent overcharging. Without the engine, the battery must supply the entire load, which results in the discharge over a twenty-four hour period being considerably greater when the engine is shut down often than with the engine running most of the time. The initial locomotive tests showed that the engine should be run at least 70 per cent of the time to meet these discharge limitations.

A generator characteristic low enough to insure engine operation 70 per cent of the time is too low to give the battery an equalizing charge. Therefore, two generator characteristics are necessary; first, a normal characteristic for regular operation; and second, a higher or equalizing characteristic for use periodically for giving the battery a gassing charge.

The minimum size of the battery is fixed by traction motor characteristics and weight of the locomotive on one hand and speed requirements on the other. The former determine the maximum current which may be drawn from the battery as limited by adhesion, and the latter the number of cells. With traction motors in parallel, the total current values on the New York Central locomotive at various adhesions are approximately as follows:

Adhesion	Amperes
25 per cent	3,700
20 per cent	3,100
15 per cent	2,500

The battery selected for this locomotive must be large enough to deliver these currents and to carry successfully at least 4,000 amperes for a period long enough to blow the 2,500-ampere battery fuses. Because of the decreased available capacity of the battery at high discharge rates, it is not practical to operate this type of locomotive on internal power at high adhesion and high speed for any great length of time. However, the extreme load conditions given above are possible and must be successfully met for short periods in practical operation.

In case of necessity it is possible to operate the three-power locomotive at high adhesion over considerable distances by running at reduced speeds with the motors in series or series-parallel. In such cases the current to the motors is reduced to ¼ or ½ of the value which would be required with the motors in parallel for the same total tractive effort. As the engine-generator set will continue to deliver its full power, all of this reduction in current is taken from the battery discharge rate, thus greatly increasing its available capacity. In addition to this, the increase in available kw-hr. capacity of the battery increases the duration of the movement and to this extent increases the kilowatt hours delivered by the engine, thus further increasing available mileage.

For fast and responsive operation of the locomotive it is advantageous to have the battery voltage near the rated voltage of the traction motors.

Battery short time current rating—2 minutes—3,000 amperes.
Engine horsepower—300.
Assumed time engine running—85 per cent.
Maximum amount battery may be discharged in 24-hour period, 125 per cent of capacity at 6-hour rate which is equivalent to the following:
  812 ampere hours in 24 hours.
  271 ampere hours per 8-hour shift.
  114 kilowatt hours per 8-hour shift, (average discharge voltage 420).

Fig. 2—Location of Apparatus on New York Central Locomotive

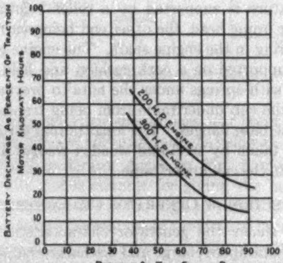

Fig. 3—Relation of Battery Discharge to Time of Engine Operation

Curves showing time oil engine is operated plotted against battery discharge as per cent of motor kilowatt-hours for initial New York Central locomotive in heavy switching service

SELECTION OF INTERNAL POWER PLANT FOR THE NEW YORK CENTRAL LOCOMOTIVE

As a result of the initial New York Central locomotive tests and the weight and speed considerations just outlined, a design for the New York Central locomotive was adopted to which the following data apply:
(See Table I also.)

Fig. 3 shows the effect of the time the engine operates upon the battery discharge. These curves are plotted from data taken during the tests on the initial New York Central locomotive. For the 300-hp. curve a number of points was secured between 45 and 75 per cent operation, the curve being extended somewhat beyond these values upon reasonable assumptions for 0 per cent and 100 per cent engine operation. The 200-hp. engine curve is based largely on assumptions since only one point (93 per cent) was available from the test data, this test being made by setting the fuel finger of the oil engine governor to limit the engine output to 200 hp. It is apparent, however, that this curve will intersect the ordinate with the engine running 0 per cent of the time at the same point as the curve for the 300-hp. engine, and, hence, should draw nearer to the latter curve as the per cent of the time the engine runs is decreased. Therefore, it is believed that the curve approximately represents the condition that would exist for a 200-hp. engine.

Fig. 3 shows that with a 300-hp. engine running 85 per cent of the time, the battery discharge will be equivalent to approximately 15 per cent of the power delivered to the traction motors. Therefore, the maximum average work which the locomotive can do per 8-hour shift when operating 3 shifts per day on internal power is: 114/0.15 = 760 kilowatt hours. Using Fig. 3 and interpolating for the 250-hp. engine, the following maximum kilowatt hours per shift may be calculated for different engine sizes using the present 301-kw-hr. battery:

Engine hp.	Maximum kw-hr. per shift
300	760
250	531
200	403

From this it appears that a 250-hp. engine might have been used successfully with the 301-kw-hr. battery to meet the requirement of 500 kw-hr. per shift. However, it was thought advisable to allow some margin for contingencies, a 25 per cent margin giving a maximum of 625 kilowatt hours, and with a 250-hp. engine, this would require a battery of approximately 355-kw-hr. capacity. The combination of a 300-hp. engine and a 301-kw-hr. battery was finally chosen because of the greater margin of capacity per shift as well as the ability to use an oil engine which had been thoroughly proved in railway service.

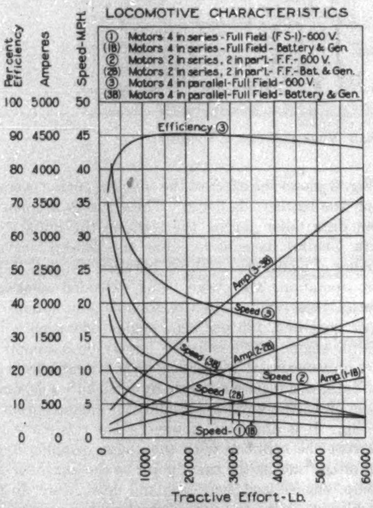

Fig. 4—Speed-Tractive Effort Characteristics of New York Central Locomotive

Fig. 4 shows locomotive characteristics on both external and internal power.

Description of Internal Power Plant of New York Central and Delaware, Lackawanna & Western Locomotives

The oil engine is the Ingersoll-Rand 300-hp., vertical, 6-cylinder, 4-stroke cycle, trunk piston, single acting type with direct fuel injection. The engine is controlled by a constant speed governor which regulates between 550 r.p.m. full load and 575 r.p.m. no load. The engine is directly connected through a flexible coupling to a 6-pole, self-excited, compound wound, 200-kw. generator of the single bearing type, with multiple self-ventilation. The generator frame is bolted to a bracket on the engine and is also supported by springs resting on the floor. The commutator end of the armature is supported by a roller bearing in the generator frame head, the other end being carried by a pilot bearing in the engine shaft. The engine-generator unit is supported on a cork cushion and held in place by bolts with springs under the nuts to prevent deflections of the cab underframe from being transmitted to the engine base flanges. The longitudinal thrust of the engine is taken by steel and wooden wedges and shear lugs cast in the cab underframe.

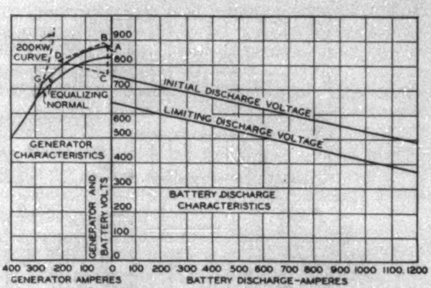

Fig. 5—Battery-Generator Characteristics of Delaware, Lackawanna & Western Locomotive

Selection of Generator Characteristic

Fig. 5 shows the generator characteristic and the battery voltampere charge and discharge characteristics of the internal power plant of the Delaware, Lackawanna & Western locomotive. These characteristics are representative of three-power locomotive practise and will be explained. When the battery is fully charged, any rate of charge however small will produce gassing, and if the charging rate be high enough, gassing will occur with the battery in any state of charge, although the rate may be reduced during the latter part of charge to a value which, unless abnormally sustained or occurring too frequently, will produce so small an amount of gassing as to be practically harmless. This value is called the "finishing rate" and is point *B* in Fig. 5. The charging rate at the end of charge should be confined between the finishing rate and one-half of the finishing rate. Consequently, line *A B* represents the voltampere charge characteristic of the battery at finish of charge condition. The ability of the battery to absorb high charging rates at the start of charge is indicated by point *D* which is the maximum charging rate recommended, and hence line *C D* is the voltampere charge characteristic at start of charge condition. Line *D B* represents the theoretical generator characteristic which would charge the battery in the minimum time and *A C* that which would produce a constant current charge at one-half the finishing rate. Therefore, the area *A B D C* includes all values of current and voltage that may be used to charge this battery under permissible conditions and the generator characteristic should intersect lines *A B* and *C D* and lie between lines *B D* and *A C*. The generator characteristic is also restricted by the 200-kw. output curve of the engine-generator set. To allow delivery of approximately full engine load over the whole range of battery discharge, the generator characteristic should pass near point *G* and lie close to the 200-kw. curve at voltages below G.

The higher generator curve in Fig. 5 meets these requirements and is suitable for giving the battery an equalizing charge, but is too high to permit the engine to run a sufficient percentage of the time to keep battery discharge within the daily limit of 125 per cent of rated capacity without overcharging the battery. Therefore, the lower curve is used for normal charging and the higher characteristic for periodic equalizing charges. The charging rate at the end of charge, when using the normal characteristic, is less than one-half the finishing rate, but with a properly shaped characteristic and the engine running almost continuously, the battery will be maintained between equalizing charges in a satisfactory state somewhat below full charge. Use of the low generator curve for normal charging has the further advantage of leaving margin for variation of characteristic between inspections without running the risk of overcharging the battery seriously, such as would happen, for example, if the engine speed increased and the equalizing characteristic were being used in daily operation.

The control is arranged so that whenever the locomotive is operating on internal power and *the traction motors are connected to the battery generator bus*, the higher characteristic is automatically brought into operation. This is permissible because usually the traction motor load is sufficient to hold the generator voltage below the point where high charging rates will occur unless the battery is in a very low state of charge. This arrangement permits the use of a more drooping curve without dropping the traction power characteristic below the point *G*. The necessity for a drooping curve may be better appreciated when it is considered that the battery is intended to deliver only 42 per cent of its capacity per 8-hour shift, whereas a generator characteristic lying along the line *B D* would give the battery a complete charge in 4 hours if continuously applied from full discharge and neglecting the small auxiliary load.

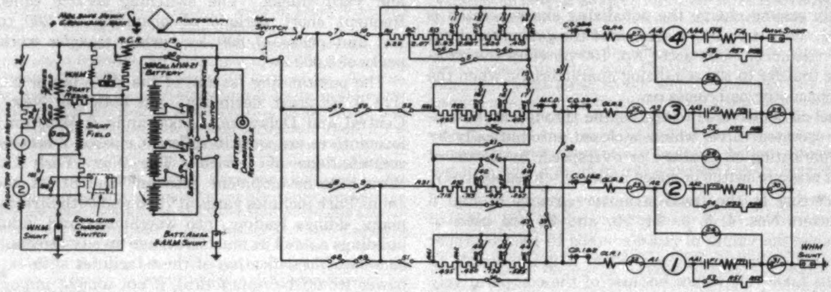

FIG. 6—POWER CIRCUIT CONNECTIONS OF DELAWARE, LACKAWANNA & WESTERN LOCOMOTIVE

CONTROL OF THE INTERNAL POWER PLANT

Both the New York Central and Delaware, Lackawanna & Western locomotives have a three-speed control on internal power. The series or lowest speed connection develops maximum tractive effort with minimum current from the battery-generator unit, allowing most slow switching movements to be made almost entirely on the engine-generator set without using battery current.

Fig. 6 shows the power circuit connections of the Delaware, Lackawanna & Western locomotive. Contactors Nos. 7, 8, 9 and 10 connect the traction motors to external power, and Nos. 47, 48, 49 and 50 to internal power. On both the New York Central and Delaware, Lackawanna & Western locomotives, transfer from external to internal power is controlled by a potential relay and is automatic upon loss of external power, although the automatic feature is selective on the New York Central locomotive because of interruption of power on third rail gaps when transfer to internal power is not desired. On both locomotives, transfer from internal to external power is accomplished by turning the controller handle to the off position and then notching out, necessitated because of going from a lower to a higher voltage power source. Indicating lights show whether operation is from internal or external power and whether collector shoes or pantograph are in contact with the third rail or trolley wire. The battery may be broken up into four sections to limit the maximum voltage to ground when doing any work in the battery compartments. The engine is started by motoring the generator from the battery through contactor No. 20 and the starting resistance; maximum field for starting is secured by short-circuiting the generator shunt field resistance with contactor No. 101. The reverse current relay controls contactor No. 19 and connects the generator to the battery when the proper generator voltage has built up; it likewise disconnects the generator should the generator voltage drop below that of the battery due to loss of engine speed, generator field, etc. To give the battery its weekly gassing charge the equalizing charge switch is closed, short-circuiting a section of the generator shunt field resistance. Contactor No. 100 provides the automatic transfer to the equalizing characteristic when the traction motor load comes on.

Fuel oil is delivered to the engine through an electrically operated valve, which is closed automatically by low lubricating oil pressure or overspeed, by means of an oil pressure switch or speed limit switch respectively.

Referring to the traction motor circuits in Fig. 6 contactors Nos. 4, 5, 6, 34, 35, and 36 are used to rearrange the values of resistor steps to secure proper operation on internal power, when it is impossible to use the 3,000-volt values because of the comparatively low battery voltage. The same rheostat values are used on both internal and external power on the New York Central locomotive because the voltages are near enough together. The control of the battery-generator combination is almost identical with that on the Delaware, Lackawanna & Western locomotive.

AUXILIARIES

Auxiliaries on the New York Central locomotive operate automatically from the third rail when available, but on the Delaware, Lackawanna & Western locomotive these run at all times on internal power as this scheme is simpler and less expensive than furnishing auxiliaries for 3,000-volt operation.

Operating cabs are heated by hot water from the oil engine cooling system. Electric immersion heaters operating from third rail are used on the New York Central locomotive to heat the cooling system water for cab heating as well as prevention of freezing when working on external power. The Delaware, Lackawanna & Western locomotive has 3,000-volt heaters for trolley operation.

SERVICE CONDITIONS

Tests on the first New York Central locomotive were confined to internal power operation and the results of these tests have been covered under *General Requirements of Internal Power Plant.*

Tests were made on the Delaware, Lackawanna & Western locomotives in a combination of transfer and switching service. The transfer work consists of hauling heavy trains at relatively high speed on external power between Secaucus and Jersey City Yards, a distance of 3½ miles. The switching, done entirely on internal power, consists of hauling these trains into the yards, partially breaking them up, making up outgoing trains, charging the train line, and hauling them to the electrified tracks. The ratio of the average power required in the switching work to that in the transfer work proved to be approximately 50 kw. to 450 kw. or 1 to 9. It is believed that this is the first case where actual data have been obtained which show the relative amount of work done on the main and yard tracks. The switching service called for frequent short periods of operation at 200 to 400 kw. and peaks of 800 kw., while transfer work had peaks of 3,000 kw.

The outstanding feature of the three-power locomotive is its great flexibility. On both the New York Central and Delaware, Lackawanna & Western these locomotives are used in different classes of service and combinations of service. The New York Central West Side development between 72nd Street and St. Johns Park includes yards at 72nd and 30th Streets with many sidings leading into warehouses and industrial buildings as well as much trackage on city streets. The complete electrification of these facilities with external power would be impractical, if not almost impossible; yet the service demanded a self-propelled locomotive capable of handling the heaviest type of switching and short transfer work, as well as road freight and transfer service on third rail. The three-power locomotive was developed to meet these requirements.

This locomotive has a field of its own and is not intended generally to supplant the straight oil or gas electric unit. The work of the locomotive when operating on internal power must be sufficiently intermittent to allow the battery to be maintained in a satisfactory state of charge. Heavy switching and short heavy transfer work on internal power or a combination of both, together with external power operation, offer conditions for which this type of locomotive is best suited. The internal power feature makes this type approach a "universal" locomotive for road freight, transfer, and switching service on sections of road which, for economic or practical reasons, could not be completely electrified.

ACKNOWLEDGMENT

The authors gratefully acknowledge the assistance rendered by Mr. W. S. H. Hamilton of the New York

Central Railroad and Mr. D. P. Orcutt of the Electric Storage Battery Company in the preparation of this paper. The original analysis of the tests on the initial New York Central locomotive by Messrs. Hamilton and Orcutt has been largely drawn upon. The discussion of the selection of generator characteristics is based on an analysis of this subject by Mr. J. H. Tracy of the Electric Storage Battery Company, to whom thanks are extended for the use of this material as well as valuable comments.

Discussion

W. S. H. Hamilton: This discussion is confined to the three-power locomotives used by the New York Central around New York City.

Some question has been raised as to the size of internal power plant required on these locomotives and also whether with the present power plant they are capable of meeting emergency conditions.

The size of the internal power plant was based on the requirements in our 60th Street yard where there is heavy switching and float work. It was estimated that to do the work quickly, internal power equivalent to 900 engine hp. should be available. This makes the locomotives "snappy" even in heavy work and lets them kick and drop cars without difficulty.

It should be borne in mind that while switching service averages only about 60 kw-hr. per hour input to the traction motors, peak inputs of 600-800 kw. are frequently encountered. They are of short duration and do not represent many kw-hr. in the course of a trick. While the lack of this amount of power would only make a small difference in time in each movement, where it was required, at the same time these small differences are cumulative and have an effect on the total work done in the trick. Furthermore, in congested yards slowing down one movement even a little usually affects movements of two or three other locomotives.

There are other locations on the West Side where this amount of power is not required and where a lighter locomotive could be used but it was desired to have all locomotives alike to increase the utilization, decrease the number of spares, and relieve the yard forces of having to worry about which locomotive to get ready for each job.

As to the adequacy of the internal power plant to stand overloads or conditions not anticipated, I wish to point out that from August 1930 until June 1931, these locomotives handled 2,000-ton trains in regular road service on internal power from 72nd Street to Spuyten Duyvil a distance of about 8 miles. This should be ample demonstration of their ability, as they are not intended regularly to handle such service and with the installation of third rail down to 72nd Street, this service has been discontinued.

The assignment of these locomotives is approximately as follows:

30th Street Yard	11
60th Street Yard	11
Hudson Side-Electric Division	8
Harlem Side-Electric Division	3
In Shop	3
Total	36

The locomotives at 30th Street operate entirely on internal power, those at 60th Street mostly on internal power and the others mostly on third rail. Those assigned to the Hudson and Harlem Sides of the Electric Division are used for express trains, way freight trains, and as traveling switchers. These latter do the industrial switching, picking up and dropping cars at various stations on internal power and then run to the next station on external power. There is a number of industrial plants where it would be very difficult to install either third rail or trolley and yet a locomotive switching them must be capable of moving rapidly between stations in order to keep out of the way of other traffic.

For such service the three-power type of locomotive is ideally suited and is a very economical solution of the problem. It should be pointed out that at the continuous rating of the traction motors, these locomotives develop 1,300 hp. at the wheel rim on external power, whereas on internal power they develop only 682 hp. To duplicate the amount of power developed on external power, a 1,600-hp. engine would be required.

For the year 1931, the whole fleet of 36 locomotives was in service with crews on 61 per cent of the time, and available for service 85.5 per cent of the time. This performance with new locomotives and new crews, we consider very creditable, but look forward to bettering it as everyone becomes more used to them.

D. P. Orcutt: Information has been asked regarding the expected life of the battery on three-power locomotives and in this connection the fact was mentioned that in an investigation of a proposal for the use of a large straight storage battery locomotive for switching service, it was found that the battery life had been stated to be 4 years and that this life had resulted in an excessive battery maintenance cost for the work under consideration.

It should be remembered that with a three-power locomotive operating on internal power, a very large part of the energy used by the motors flows directly from the generator to them and does not pass through the battery.

Data collected from the operation of the first three-power locomotives on the New York Central, No. 1525, showed that in switching service about 85 per cent of the energy used by the traction motors flowed directly from the generator to the motors and 15 per cent from the battery to the motors. It is therefore evident that a very much smaller battery can be used with a three-power unit, thus greatly reducing battery maintenance cost from what it would be with a straight battery locomotive in switching service.

Incidentally it may be stated that this same data obtained from No. 1525 showed that the losses in the battery amounted to only about 5 per cent of the total energy generated while in a straight battery unit the battery losses would probably exceed 30 per cent of the energy required to keep the locomotive in service.

A straight battery locomotive may be the most economical unit to use under conditions where the size of the battery necessary to do the total amount of work does not require more battery weight than can be placed on a locomotive of the total weight required and where time is available for recharging the battery. In neither of the installations discussed by Messrs. Brehob and Craton would a straight battery locomotive give the required service which includes 24-hour operation as well as heavy transfer service.

The economies resulting from the use of any form of internally powered locomotive for use with an electrification project can be determined only by a comparison of the quality of service made available and of the cost of the entire service under consideration. A study based only on the cost of locomotive operation per hour does not give a true picture of the economies effected on the whole project.

As the paper and the discussion are confined to locomotives capable of operating on both external and internal power, we have combined data obtained from both the D. L. & W. three-power locomotives and New York Central three-power locomotives and in this way obtain the following as being approximately representative of this type of locomotive operating in connection with a railroad electrification project:

In an 8-hour shift the locomotive would operate on non-electrified tracks approximately 6 hours at an average input to the motors of 60 kw. per hour which would represent a total of 360 kw-hr.

On electrified tracks it would operate approximately two hours at an average input to the motors of 450 kw-hr. per hour which would represent a total of 900 kw-hr.

The power required for auxiliaries and all electrical losses during this 8-hour period would represent about 220 kw-hr. making the total power required for the locomotive for the 8-hour shift approximately 1,480 kw-hr.

Approximately 15 per cent of the 360 kw-hr. delivered to the motors on internal power while the locomotive is on non-electrified tracks would come from the battery or 54 kw-hr. This represents only about 4 per cent of the total power required by the locomotive during the 8-hour shift. As compared to this a straight battery locomotive would have had to deliver all the power required by the locomotive if the locomotive were to do the same work that the combination locomotive did during this 8-hour shift.

It can easily be seen, therefore, that when only 4 per cent of the work which this combination locomotive does in an 8-hour shift comes from the battery, that battery costs will be a relatively small proportion of the total operating costs of the locomotive as compared with a type of locomotive in which all the work is done by the battery.

Even when called upon to operate entirely on internal power the input from the battery to the traction motors is only 15 per cent of the total input to the motors whereas it would have to be 100 per cent (plus input to auxiliaries) in a straight battery locomotive.

It has been pointed out that this locomotive has decided advantages in connection with an electrification project:

It can be operated in warehouses and other places where it may be objectionable to run an internal combustion engine or install third rail or trolley.

It is capable of accelerating rapidly.

It is the most flexible type of locomotive tried out or suggested for this class of service.

It has high fuel economy because the engine operates with a favorable load factor.

It is our belief that the battery costs on this locomotive have been and will be entirely justified by the advantages obtained.

Hermann Lemp: To design an oil-engine required only to operate at nearly constant load and speed is a much simpler problem than to design one for adjustable speed and load, as anyone conversant with oil-engine design will readily appreciate. Similarly a storage battery, floating on a system, receiving and delivering energy continuously, on a hand to mouth proposition operates under a far better condition than when first fully charged then full discharged sometimes way down to the very lowest figure permissible. It is therefore quite conceivable, as Mr. Orcutt pointed out, that the storage battery manufacturer's guarantee of four years life can be met. This combination, when used in switching service, permits the time load factor of 15 per cent to be exchanged for 62 per cent and hence requires a smaller oil engine to perform the work of a bigger unit.

Mr. Brehob laid particular stress on the necessity of providing heavier axles and frames owing to the addition of the internal combustion engine plant, while he made no mention of the weight of the storage battery. If my records are correct the weights of the first three-power locomotives were as follows:

Total weight—257,000 lb., in which the battery weighs 34,300 lb. and oil engine generator and accessories weigh 31,500 lb.

In other words another engine equipment of 300 hp. would not cost and weigh any more than the battery, good only for four years, while the engine equipment, if properly maintained, would be available at least for ten years. To me the question is therefore one of original investment.

Railroads I think are particularly anxious to obtain an equipment which can maintain the rated output substantially continuously and which is not limited by a "time power decrease," such as a battery under a continuous full discharge rate would constitute. A similar operating condition is presented by the Hoboken Manufacturers Railroad. Most of the switching can be performed by a 300-hp. unit. But sometimes during the day, particularly when the tide is low and loaded cars have to be pulled up a stiff grade from the float, a second 300-hp. engine in reserve is started up and gives the additional power and acceleration needed. The engine units *A* and *B* are shifted every day, so as to equalize the time service of each. Such a locomotive, when climatic or service conditions call for nearly continuous full load operation, can give such a service at a lower first cost and maintenance than the battery combination.

Mr. Hamilton has expressed a fear that the oil-engine part of the equipment might prove unreliable. He stated that the actual experience with the three-power locomotive had demonstrated an availability for service of 85.5 per cent. It was brought out in a paper read by the writer before the Metropolitan Section of the A.S.M.E., April 17, 1928, that the average availability of straight oil-electric locomotives using the same oil-engine unit as the three-power locomotive had been established to be 91.5 per cent. This figure was obtained from returns to a questionnaire sent to all railroads and industrial plants using these locomotives for about three years in various locations and service.

F. H. Brehob: Due to the fact that the service requirements to be met were severe and the type of locomotive to be built was of unusual design, a number of difficult problems in mechanical design had to be solved.

The locomotive as developed represents the heaviest four-axle swivel truck locomotive in service today, and utilizes the heaviest axle loading using single-geared axle-hung motors.

Naturally, the railroad desires no more weight in a locomotive than is absolutely necessary to obtain the required adhesion for the maximum load to be handled. Generally, the basic design of the ordinary straight electric freight locomotive results in approximately the desired weight. By basic weight I mean using normal stresses and using the kind and grade of material ordinarily used for the various parts. For example, on the New York Central R-2, six-motor freight locomotive utilizing the same traction motor as on the three-power locomotive, approximately 2½ per cent of the total weight of 266,000 lb. is ballast.

The three-power locomotive as furnished the New York Central is not only a straight electric locomotive converting electrical power into mechanical power, but carries in addition a power plant with its accessories such as water tank, fuel tank, radiators and piping. The weight is thus considerably increased due to this apparatus and also to the increased weight of the mechanical portion requiring heavier supporting members to carry this load and because of the necessity of building a larger locomotive to house this apparatus. The railroad specified a minimum weight of 125 tons. By utilizing material to best advantage, reducing sections of material where feasible, and in one or two cases using a higher grade of material, it was possible to limit the weight in working order to 257,000 lb. For example, the axles were made of vanadium steel, although the selection of this material was also influenced by a limitation in the diameter of the axle to 8 in. so that the GE-286 motor used on other locomotives on the New York Central could be utilized without change on the three-power locomotive.

One of the most effective ways of keeping the weight to a minimum is to design the locomotive as compactly as possible which involves a suitable arrangement of apparatus using every bit of space to best advantage. The apparatus must be arranged to be readily accessible for inspection and repair and for easy removal from the locomotive.

The arrangement finally adopted was the one as illustrated in the paper. It will be noted that the blowers for ventilating the traction motors are placed directly over the hollow center plate into a small space recessed into the battery compartment although the upper tier of batteries is not affected. The control apparatus is mounted along one side of the locomotive opposite the engine, access being obtained from one side by removable covers on the outside of the cab. In this manner the space between the engine and the control equipment serves a double purpose; on the one hand giving accessibility to the engine for maintenance and on the other hand providing the necessary arcing clearances for the contactors. The space between the trucks is practically all taken up with the accelerating grids and the air compressor. The space not required on the roof for the hatch is occupied with engine radiators, and air reservoirs. Utilizing all the available space to advantage permits building the locomotive as short as possible with a minimum distance between center plates resulting in a minimum cross section of material in the supporting underframe, and consequently a minimum weight of material.

Owing to the fact that collection of power on the D. L. & W. locomotive is from a 3,000-volt overhead trolley, the arrangement of apparatus is somewhat different. It was desirable to enclose the 3,000-volt control apparatus somewhat more than the 600-volt apparatus on the New York Central three-power locomotive, for the sake of safety and cleanliness. This resulted in an arrangement whereby the engine was placed in one side of the cab leaving a greater space for the high-voltage equipment opposite the engine. This also permitted the use of enclosing covers on the inside as well as on the outside. Instead of locating the rheostats beneath the locomotive they were placed inside the locomotive immediately above the floor, and chimneys for heat dissipation were provided. The space underneath was used for air reservoirs instead of the roof, thereby providing space for mounting the overhead trolley. The battery trays were arranged in three tiers due to the fact that this battery was of a higher voltage and consisted of a larger number of smaller cells.

Another reason for arranging the apparatus as compactly as possible was to obtain a design which would negotiate the minimum radius of curvature of 100 ft. required by the railroad. This severe curvature is the principal reason for the swivel truck design as it is doubtful whether an articulated type could have been built which would prove successful.

Certain definite height and width limitations had to be met by the railroad, and these had to be considered especially on a curve when a displacement from normal position is encountered. This was not an easy matter to accomplish because a straight electric locomotive required to negotiate the same curve would be shorter. The design required that the distance between center plates be kept to a minimum and of even greater importance that the overhang from the center plate to the end of the coupler be kept at a minimum.

The draft rigging is, in effect, radial in that the coupler is free to swivel in a coupler extension which also swivels.

The three-power locomotives for the New York Central and D. L. & W. railroads are a modification of the original three-power locomotive jointly designed by the American Locomotive Company and the General Electric Company, and the operating experience gained by the New York Central on this locomotive and straight electric locomotive has been most helpful. It is gratifying that the combined efforts of the railroad and builder produced a new type of motive power which in a relatively short length of time has already proven successful.

F. H. Craton: Space limitations in the paper did not allow much detail regarding the interesting background behind the development of the three-power locomotive. There are 36 of these locomotives in service on the New York Central in New York, 2 on the Lackawanna and 2 on the Illinois Terminal Railroad. As the so-called West Side Improvement of the New York Central was largely responsible for the development of the three-power locomotive, it is briefly described in the following.

This project is the last step in eliminating steam locomotive operation from Manhattan Island. The New York Central's freight tracks enter Manhattan at Spuyten Duyvil which is at the northwest tip of the island at the junction of the Hudson and Harlem rivers, the line running from Spuyten Duyvil south along the east shore of the Hudson River for 12.4 miles as far as St. Johns Park. The electrification of these tracks constitutes a part of the so-called West Side Improvement. From Spuyten Duyvil to 72nd Street, which is at the entrance to the 60th Street yard, 600-volt third rail has been installed as an extension of the present third rail electric zone. The heavy freight service from Harmon, the northern terminus of the electric zone, to 72nd Street, approximately 30 miles, is handled by Class R-2 straight electric 600-volt road locomotives, 42 of which were purchased during 1930 and 1931. However, south of 72nd Street, owing to unusual conditions involving much trackage following city streets, a number of sidings entering industrial buildings and warehouses, much yard trackage and special conditions connected with float work, it was impractical to electrify with either third rail or overhead distribution systems. Therefore, the railroad management was faced with the necessity for choosing a suitable type of internally powered locomotive for the service south of 72nd Street as well as a locomotive which would operate also on third rail in order to increase its flexibility. After a detailed study of the question involving consideration of all the conditions to be met, the three-power type of locomotive was finally chosen.

Discussion of the three-power locomotive usually leads to its comparison with a two-power design, which is a unit with a straight engine-generator power plant and external power facilities. The justification for using one type or the other hinges entirely on the service requirements to be fulfilled and can be determined only after a thorough study of all the conditions involved. A power plant of the engine-generator-battery type is best fitted for operation in service in which the peak demands are high and the load factor low. The operating conditions on the New York Central West Side as well as the Lackawanna are well suited to take advantage of this type of internal power plant. The three-power type possesses the advantage of being able to operate on battery power into buildings or restricted areas where there might be an objection to an internal combustion engine because of sparks or odor, but the value of this feature would be dictated by the service requirements.

The question has been raised as to whether the internal power plant should be regarded as an auxiliary to the external power operating facilities or vice versa. This appears to be dependent upon the service conditions under which the locomotive operates on each particular application. Because of the unusual flexibility of this type, it is possible that the predominance of one type of operation over the other would shift from one to the other in operation on a single diversified application such as the New York Central where the locomotives are used with different combinations of external and internal power operating conditions but all units are interchangeable in the various classes of work.

F. H. Brehob and F. H. Craton: If the term "power plant" as referred to in the discussion has been misunderstood, it should be stated that this term includes the battery inasmuch as the battery and engine generator in multiple combine to furnish power to the traction motors. It was realized that the battery presented a design problem on account of its weight, which is one reason the battery was divided, one-half of it being placed almost directly over each center plate, where its weight would require a minimum amount of supporting structure.

Mr. Hamilton has pointed out that a locomotive without a battery would require additional engine-generator capacity together with additional accessories. This additional weight of power plant in the form of engine-generator, radiators, etc., would offset the weight of the battery.

The two-power locomotive undoubtedly has its place in the field of transportation. By two-power is meant a locomotive which will first operate from external power and secondly from an engine-generator set, but without battery for traction purposes. We believe the selection of either type can only be satisfactorily arrived at when all the service requirements to be performed are known and studied.

Motors for 3,000-Volt D-C. Multiple Unit Cars

BY JOHN C. AYDELOTT*
Member, A.I.E.E.

A NEW multiple unit car motor, incorporating many novel features of design, was developed for the electrification of the suburban service of the D. L. & W. R. R. The absence of trouble, in commencing service and in maintaining it, marked the whole electrification program. This was the first installation of multiple unit suburban service in this country employing a trolley potential of 3,000 volts direct current.

Locomotive motors to operate from a 3,000-volt trolley were first built for the C. M. & St. P. R. R. in 1914 and subsequent installations include the Spanish Northern Railway in Spain, the Paulista Railway in Brazil, the Mexican Railway in Mexico and the Cleveland Union Terminals Company. Experience gained from several years of operation with the earlier designs of 3,000-volt locomotive motors has been invaluable in perfecting the design of the Lackawanna multiple unit car motor which rounds out the line available for 3,000-volt d-c. electrification.

There are now in service on the Lackawanna Railroad 564 of these motors. The breaking in of equipments started in August, 1930. Revenue service started September 3, 1930, when the first passenger-carrying train ran from Hoboken to Montclair. With the final extension to Dover on January 25, 1931, the last of 141 units was placed in service. Traffic has so increased that units originally intended as spare cars are all needed regularly and there are times during the day when all but three units are on the road.

By June 1, 1931, 4,500,000 car-miles had been operated with only two train delays, one of 19 minutes and one of 4 minutes, chargeable to motor failure. One train was held at Hoboken Terminal 19 minutes due to a burned out armature bearing and the other was 4 minutes late arriving at Montclair.

During the period of initial operation these motors have been remarkably free from flashovers, insulation failures, and mechanical troubles.

The minimizing of motor flashing is an achievement embracing many features of motor design. Flashing may be caused by interruptions or disturbances in the voltage supplied to the motors, and many things within the motor itself may contribute to motor flashing, such as poor commutator condition, commutator roughness, oil and dirt between commutator bars, flat spots, bouncing brushes, and low motor stability.

The Lackawanna motor has 281 commutator segments. With 1,500 volts applied to the motor terminals there is an average of 21.3 volts per bar. The successful operation of this motor demonstrates the feasibility of high volts-per-bar, higher than previously used in any 3,000-volt railway motor, and depends upon commutating characteristics that will keep the commutator always in first class condition, and upon the ability of the motor to withstand frequent wide and sudden variations of trolley voltage on full or weak field with a minimum of spit at the brushes.

Good commutation hinges first upon keeping the reactance of the armature conductors at a minimum so that the energy involved in the reversal of the current in a conductor is low. Then the compensation, depending upon the quantity of commutating pole flux, must have the required value at all loads. The design of this motor employs a one-turn armature winding. Careful attention was given to the number of slots and the proportions of the slots, air-gap and pole faces. The armature bars are clipped at the back permitting a "breaking up of the slots" which has long been a feature of good railway motor design. Non-magnetic steel binding wire is used to reduce slot reactance. At light loads the effect of non-magnetic binding wire as compared with steel binding wire is particularly noteworthy. With non-magnetic binding wire the slot reactance flux and slot reactance are not only low in value but are essentially proportional to load current. .With steel wire the slot reactance flux is proportionately very high at light loads until the binding wire saturates and is increased by the amount of flux carried by the wire at all loads. When the slot reactance voltage is not proportional to load it cannot be correctly compensated at all loads.

It is well known that good commutation can usually be obtained at some one motor load according to the adjustment of the commutating field strength and it has been common practise to adjust compensation for minimum sparking at some load around the one-hour rating. If the commutating poles were somewhat saturated at this point the motor would be over compensated for all lighter loads. The design of this motor includes ample commutating pole cross section. Commutation is good from the lightest load to four times the continuous rating. Light loads are mentioned particularly because no sacrifice of commutation at light loads has been made to obtain correct compensation at heavy loads.

This motor has ability to withstand flashover from interruption to an unusual degree. This may be attributed largely to the use of highly responsive commutating poles. Extra turns are wound on the commutating coils and the extra magneto-motive force is consumed under steady load condition in non-magnetic shims at the back of the commutating pole pieces. Thus the commutating pole flux follows very quickly any change in the armature current and tends to maintain correct compensation even under extreme transient conditions.

---

*Trans. Engg. Dept., General Electric Co., Erie, Pa.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

A strong exciting field winding adds to the stability of the motor. The use of an inductive shunt rather than field tapping to obtain weak field gives any motor a greater ability to withstand flashover from interruption during reduced field operation. In the case of the Lackawanna motor the inductance of the field shunt has been so proportioned that the ability of the motor to withstand flashover from interruption on reduced field is superior even to its performance on full field.

Motor flashing that might be caused by dirt is avoided by the ventilating scheme developed for this motor. Dirt may lodge between commutator segments causing short circuits which, especially with high volts per bar, will lead to flashovers. Dirt that causes brushes to stick in the holders inevitably leads to flashing. It is also highly desirable that all other parts of the motor as well as the commutator and brushholders be kept as free from dirt and moisture as possible.

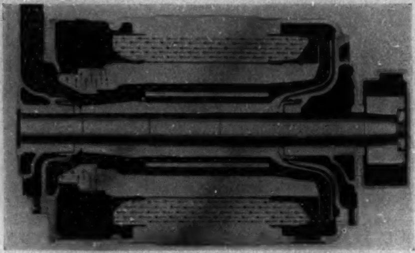

Fig. 1—Ventilating Scheme for D. L. & W. R. R. Motor Showing Air Circulation Inside the Frame

The most successful 3,000-volt locomotive motors have been blown, clean air being taken from the cab; and a blast of air has been directed straight against the motor commutator serving to prevent any accumulation of dust from the brushes in the mica grooves. The increased pressure in a blown motor tends to prevent the entrance of brake shoe dust or other dirt, or snow from the lower levels of the air surrounding the running gear of a locomotive in motion.

No external blowers are used on the D. L. & W. multiple unit cars but with the system of ventilation used the motor frame operates at all times either at or slightly above atmospheric pressure. The motors are self-ventilated as shown in Fig. 1. The cooperation of the car builder permitted the ventilating air to be taken from settling chambers over the vestibules to which it is admitted through louvers at each corner of the car roof. A separate duct to each motor goes down through the side and along under the floor of the car to a point over the commutator end bearing as shown in Fig. 2. A flexible air connection made of cloth sewed over a coiled wire leads the air from the duct on the car to the motor inlet in the commutator end framehead. The flow of air is maintained by a fan on the motor shaft. The air enters the motor under the commutator and passes first through the ducts in the armature. It is then returned by the fan through the field structure of the motor and exhausted at the commutator end. The air outlet opening is covered with an expanded metal screen and a hood so that foreign material cannot fall or be thrown into the motor. This method maintains pressure inside all the exposed surfaces of a self-ventilated motor, which means that track dirt, fine snow, or brakeshoe dust cannot enter the motor. It should also be noted that before the ventilating air reaches the commutator chamber of the motor it is filtered, so to speak, through both the armature and field coils. Furthermore, any carbon dust that originates in the commutator chamber is carried directly to the exhaust openings and does not enter any other parts of the motor. Routine inspections have shown these motors to be unusually clean. Surplus oil from the bearings is led through ducts to the outside of the motor and none finds its way inside.

Fig. 2—Ventilating Scheme for Motor Car Showing Air Intake at the Roof and Path to Motors

Smooth commutators depend not only on good commutating characteristics but also on good mechanical design and construction. The use of four brushholders and the low current necessary because of the high voltage permit the commutator to be compact and strong. The commutator diameter is 16¼ in. and there is a brush surface of 2¾ in. Six bolts hold the commutator cap and shell together. The cars operate at 70 mi. per hr. at least once during every round trip. With 35-in.

wheels and 59/22 gearing the motor reaches 1,800 r.p.m. at 70 mi. per hr. This gives a peripheral speed at the commutator of 7,620 ft. per minute.

When the motors were first put into service there was some brush breakage at high speeds but in a short time the commutators seasoned and brush breakage is now practically eliminated. The brushholders play their part in maintaining good commutating conditions. Pressure fingers are of the steel clock spring type, of low inertia, maintaining their tension permanently, and are centrally located by recessed adjusting sleeves clamped by the first turn of the springs. A non-resilient brush is used to maintain contact with the commutator at high speed. No abrasive action is necessary to keep the commutator smooth. Thus the brush may be comparatively soft, of low friction coefficient and high contact drop.

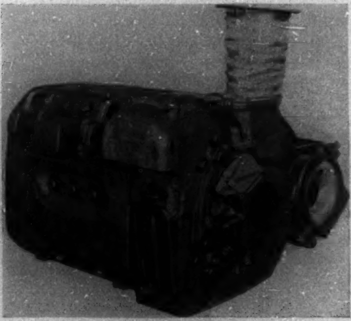

FIG. 3—GE-700-A 1,500/3,000-VOLT RAILWAY MOTOR SHOWING AIR INTAKE AND OUTLET

The insulation of the motor throughout is in accordance with recognized standards for 3,000-volt railway motors. While the absence of insulation failures in the motors thus far covers a comparatively short period, experience has shown that the same kind of insulation in other 3,000-volt motors lasts indefinitely, failures seldom occurring from any other cause than mechanical damage.

The ratings of the motors, when ventilated as in service, are as follows:

	Volts	Field strength	Shaft hp.	Amps.	R.p.m.	Rise deg. cent.
Continuous	1,500	50 per cent	181	97.0	1055	105
One hour	1,500	50 per cent	255	137.0	913	120

Although during the time that it is connected, the inductive shunt carries 50 per cent of the current passing through the motor, it has a continuous rating of only 34 amperes. The field shunt is designed with a temperature rise characteristic which at the r.m.s. current obtained in continuous suburban service will give a temperature rise approximately equal to the corresponding temperature rise of the traction motor exciting fields. Cold equipments coupled in train with hot equipments will share the load equally.

On certain length runs the r.m.s. current of the shunt slightly exceeds the rating, reaching a peak value at runs of approximately 3,000 ft. in length, where the calculated r.m.s. is approximately 37 amperes. However, under these conditions the r.m.s. current of the motor exceeds the continuous rating for 105 deg. cent. rise by resistance. Not only was the present electrification of the D. L. & W. R. R. considered in studying shunt capacity but also the possibility of extensions into more mountainous territory involving long uphill runs. These studies indicate that these runs do not require a shunt rating more than one-third the continuous motor rating for 50 per cent field strength operation. The reduction in shunt rating also permits a saving in weight.

Views of the complete motor are shown in Figs. 3 and 4. Four motors are used on a motor car weighing 81.5 tons loaded, which together with a trail car weighing 56.5 tons forms a two-car unit of 138 tons. The motor weighs complete with gear, gear case and axle linings 6,850 lb., giving a weight per horsepower of 26.9 lb. The four motors give a capacity for the two car units of 7.4 hp. per ton. Trains for use in short run commuter service may be made of 2, 4, 6, 8, 10 or 12 cars, half of which in each case are motor cars. A typical six-car train has a free running speed of 67 mi. per hr. on level track (Davis Friction) and a maximum permissible speed of 70 mi. per hr. Some of the trains shown on the time tables make the following stops and schedule speeds.

Stations	Miles	Stops	Avg. run	Schedule speed
Hoboken to South Orange	13.85	10	1.38 mi.	28.7 mi. per hr.
South Orange to Hoboken	13.85	10	1.38 mi.	29.7 mi. per hr.
Hoboken to Summit	20.10	13	1.55 mi.	30.9 mi. per hr.
Hoboken to Morristown	29.77	18	1.65 mi.	31.3 mi. per hr.
Morristown to Hoboken	29.77	17	1.75 mi.	31.9 mi. per hr.
Dover to Hoboken	40.49	22	1.84 mi.	32.8 mi. per hr.
Hoboken to Montclair	13.12	6	2.19 mi.	34.2 mi. per hr.
Dover to Hoboken	40.49	14	2.89 mi.	40.0 mi. per hr.
Hoboken to Dover	40.49	7	5.78 mi.	41.2 mi. per hr.
Montclair to Hoboken	13.12	1	13.12 mi.	41.4 mi. per hr.

The motors will permit the use of as high an accelerating rate as desired, limited only by the weight on drivers and the slipping point of the wheels. Normally an automatic acceleration of 1.5 mi. per hr. per sec. is maintained corresponding to an adhesion of 12.8 per cent. Acceleration tests have shown an equipment to be capable of reaching 30 mi. per hr. in 20 seconds and 47 mi. per hr. in 60 seconds.

In frequent stop service a four-motor equipment is well loaded by a motor car and trailer unit, and the motor heating approaches the permissible limit for class B insulation. Experience has shown that for railway motors, class B insulation will have a longer life if the motors are run hot enough to keep them free from moisture. In long run service the motors will have sufficient excess capacity to permit the handling of additional trailers. Such train make-ups as two standard units and one trailer, or three standard units and three trailers are contemplated. With such combinations the accelerating rate will be reduced but in infrequent stop service these trains will be capable of fast schedules.

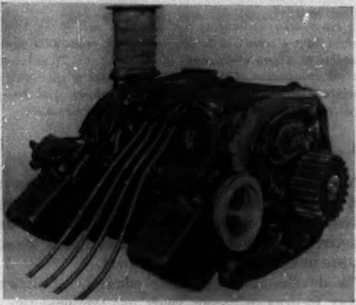

Fig. 4—GE-700-A 1,500/3,000-Volt Railway Motor Showing Pinion and Axle Preparation

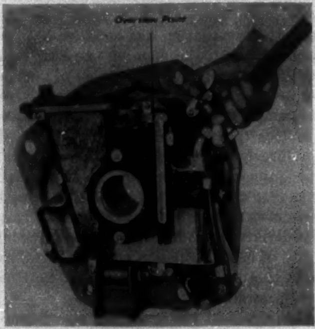

Fig. 5—Model Showing Principle of Constant-Oil-Level Bearing for Railway Motors. Oil in Reservoir at Overflow Point During Filling Operation

Conservative interpretation of experience characterizes every feature of the mechanical design, contributing to low maintenance. Stresses in all working parts are low. Both armature and axle bearings are of the sleeve type and embody the constant oil level feature permitting oiling periods to be extended to several times the usual period. There is a layer of babbitt on the wearing surfaces of the bore and flanges of all the bearings. The almost complete absence of hot bearings during the initial stages of the electrification was due not only to design, but to the fact that all of the linings were line reamed after assembly in their respective final positions and due to the careful packing of the bearings, oiling and breaking in.

In the bearings of the motor the oil level is maintained practically constant in the waste chamber as long as there is any oil in the reservoir. There are separate openings for waste and oil, hence there is no chance for dirt to fall into the waste chamber when replenishing the oil supply. The principal of operation of the constant oil level bearing is illustrated in Fig. 5 showing a view of a sectional model.

This type of bearing has been designed to operate between inspections without addition of oil. Should it become necessary to add oil on the road, the oil can be poured into the bearing through the filler opening and the bearing will operate as an ordinary bearing.

The operation of the gearing on the motors is quiet, promising long life. Gearing is of special heat treated steel, General Electric Company grade F, 2¼ pitch, with long and short addendum tooth form. The gear teeth were ground after treatment to insure correct profile. The possibility of giving off ringing notes from the gear has been overcome by a non-resonant feature shown in Fig. 6. This is obtained by snapping rings of small cross section into annular grooves machined in the under side of the rim. These rings are of a size having a different period of vibration from that of the gear section thereby counteracting or destroying the vibrations in the gear. The manner in which the rings are assembled provides an annular pocket for the retention of gear grease. This also has a decided damping effect. After assembly the rings are welded at the joint to prevent any possibility of their coming loose.

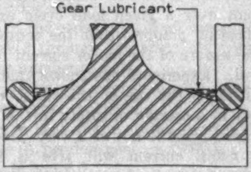

Fig. 6—Section of Non-Resonant Gear

Gear cases are of malleable iron with three point support.

Six months to a year of operation gives only an indication of what the maintenance expense will be. A longer time will be necessary before sufficient data are accumulated and ready to publish. The absence of trouble thus far, however, promises unusually low maintenance for this first multiple unit suburban electrification employing a trolley potential of 3,000 volts direct current.

Temperature Rise of Ventilated Railway Motor Armatures†

BY D. A. LIGHTBAND*
Associate, A.I.E.E.

Synopsis.—*The calculation of temperature rise and of time-temperature curves of a railway motor for which only preliminary design data are available, usually presents considerable difficulty. Modern railway practise demands increasingly large power units in a limited space, so that accurate methods are necessary for the predetermination of temperature rise as a basis for guaranteed ratings and of time-temperature curves for the application of a motor to a complicated service cycle.*

For calculating the temperature rise of the armature in a new design of motor for any time interval and load condition, the author presents a method which is shown to give consistent results when applied to motors of widely varying size. A brief outline is given of the method by which the equations are derived from the usual theory of heat flow between related bodies. It is shown that by making certain assumptions the armature can be reduced to a simple equivalent model consisting of two conducting bodies separated by an insulating wall, and that the equations resulting from an analysis of this thermal system form a practical method of calculating time-temperature curves of an armature from preliminary design data. A detailed mathematical treatment is presented in an appendix.

By substitution of existing test data into part of the formula it is shown how a curve can be obtained which renders the equations applicable to a very wide range of motor sizes. To illustrate the practical application of the formula, a number of calculated time-temperature curves for existing motors is shown and compared with data from actual temperature tests of these same motors.

* * * * *

THE accurate predetermination of temperature rise for loads of short duration in a new design of traction motor is of the utmost importance since the application of all such motors involves service of an intermittent nature. The usual method of using a r.m.s. current over a given load cycle as a basis of motor application assumes that the temperature rise varies as the square of the motor current over a given time interval. Experience has shown that this is not the case, although the use of the r.m.s. current will always result in a margin of safety in the final result. Where the load cycle is not of a very widely varying nature the r.m.s. current will give a fairly close approximation of the actual conditions. In such service as mine haulage or yard switching where a widely varying load cycle has been definitely specified by the purchaser, greater economy of space and cost can be accomplished if an accurate method is available for calculating the time-temperature curves for any load condition. Such a method can then be applied successively to each load condition of the cycle and a true picture of the motor heating will be obtained.

In many cases a motor designer is called upon to guarantee ratings which allow very little margin for guesswork in estimating temperature rise and consequently feels the need of a reliable means for its calculation. Railway motors are usually worked much closer to the limits allowed by existing insulating materials than machines used in other applications. Also, the exacting space limitations imposed upon motors placed under locomotives or rail cars, together with the present demand for still greater capacity within these limitations calls for closer designing than is generally required for other types of machine. Consequently, there is an urgent need for more accurate predetermination of temperature rise if a constant advance in the art is to be maintained.

The development of highly efficient ventilation of railway motors in recent years has rendered the estimating of short-time temperature rise more difficult than was the case with the older type of motor of larger thermal capacity. In the newer designs, the value of the nominal one-hour rating as a true indication of thermal capacity is not very great since the much more effective ventilation has considerably decreased the margin between the nominal one-hour rating and the continuous rating. The rate of temperature increase for short intervals cannot be safely regarded as the function of an unvarying time constant in a motor of this type since the rate of heat dissipation, which is largely dependent on the speed, has a considerable influence on the so-called thermal time-constant. In the following treatment a method of predetermining the thermal characteristics of ventilated motors is derived which takes into account the influence of the rate of heat dissipation on the thermal capacity as well as the dissimilar nature of the materials contained in the structure of the armature.

In a well-designed motor having an efficient ventilating system, the temperature of the armature windings will increase more rapidly than that of the field windings so that the armature is the more sensitive to changes in load. On this account it becomes essential to know the thermal characteristics of the more complicated rotor windings if a close estimate of the behavior of the motor under a varying load cycle is desired. This treatment, therefore, is devoted entirely to the more difficult problem of arriving at suitable equations from which the temperature rise of the armature can be determined for any desired load and speed.

---

*Railway Engg. Dept., Westinghouse Elec. and Mfg. Co., East Pittsburgh, Pa.

†Part of the material in this paper was submitted as a thesis to the University of Pittsburgh in 1930.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

In order to arrive at anything approaching a simple result, it is necessary to reduce the armature to the simplest possible equivalent model. Nearly all railway armatures are designed so that a portion of the cooling air is drawn through ventilating ducts running axially through the armature punchings underneath the slots. Since the axial length of the armature core is usually long in comparison to the radial depth of the punchings, the heat flow across the plane of the laminations will be very small compared to the flow parallel to the plane of the laminations. Also, the temperature of the end windings in modern railway motors is usually fairly close to that of the embedded windings over most of the working load conditions and, on account of the comparative length of the embedded part, the temperature variation along the whole length of armature winding is comparatively small. From these considerations, the following assumptions are made:

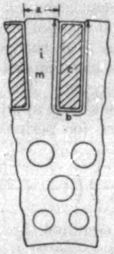

FIG. 1

A. The temperature of the copper in the slot is assumed to be uniform in all three dimensions.

B. The temperature throughout the iron of the armature punchings is assumed to be uniform in all three dimensions.

C. The rate of heat transfer to the ventilating air in the axial ducts of the core is taken as being one-half that at the outer surface. This is a purely empirical assumption and is found to give the most consistent results in the calculation of the surface heat transfer constant from temperature test data. It is also based on the supposition that the air in the ducts moves relatively to the surface of the ducts with a velocity which is about one-quarter to one-third the velocity of the air relative to the armature surface. The rate of heat transfer in axial ducts for various conditions of air velocity and nature of surface has been obtained experimentally by Luke.

D. The flow of heat through the insulation at the top of the slot is neglected.

The first two of these assumptions reduce the problem to a two dimensional one so that it is only necessary to consider the flow of heat in the armature in the plane of the laminations, that is, perpendicular to the axis of the armature. There are two main component parts of the armature, the iron of the core, represented by i in Fig. 1, and the copper c embedded in the slot. The iron and the copper, whose thermal characteristics differ from each other quite considerably are separated by a comparatively thick insulating wall m. It is the interchange of heat between the iron and the copper through this insulation that is usually neglected in most methods of predetermining temperature rise in railway motor armatures. The arrangement of the component parts of the armature as shown by Fig. 1 can be represented by the simple thermal model shown in Fig. 2. The body c represents the copper separated by the insulation m from the body i which represents the iron of the core. The equations given below are derived from the mathematical consideration of this system presented in the Appendix.

The following symbols are employed:

a = width of tooth at the armature surface in inches.
b = periphery of the slot in inches.
K_1 = rate of heat conduction through the slot insulation in watts per sq. in. per deg. cent. $= \frac{\kappa}{\tau}$
K_2 = coefficient of heat transfer from the armature surface to the ventilating air in watts per square in. per deg. cent.
κ = conductivity of the insulation in watts per in. per deg. cent.
p = sum of the peripheries of all the axial ventilating ducts through the armature core divided by the number of slots.
S_c = specific heat of copper in watt-hours per lb. per deg. cent. = 0.0485.
S_i = specific heat of the armature iron in watt-hours per lb. per deg. cent. = 0.0605.
t = time in hours.
T_c = temperature reached by the copper in time t.
T_i = temperature reached by the iron in time t.

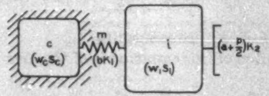

FIG. 2

T_a = mean temperature of the ventilating air adjacent to the armature surface. (It is assumed that this temperature will be the same in the vent ducts as at the armature surface.)
T_k = temperature rise of the copper above the average temperature of the ventilating air after infinite time.
τ = thickness of insulation between copper in the slot and iron at sides and bottom of slot.
θ = temperature rise of the copper above the ambient air temperature at time t.
θ_a = average temperature rise of the ventilating air above the ambient temperature at time t.
θ_c = temperature rise of the armature copper above the average temperature of the ventilating air at time t.

θ_k = temperature rise of the armature copper above the ambient temperature when t is infinite.

V = rate of air flow through the motor in cu. ft. per min.

v_s = peripheral speed of armature surface in ft. per min.

W_c = loss in the embedded conductors in one inch length of one slot in watts

W_i = core loss in watts per inch length of core per slot.

w_c = weight of copper in one inch length of one slot + 50 per cent of weight of insulating material in one inch length of slot. (In a motor insulated for 750 volts with single-turn coils this will be equivalent to 1.3 times weight of copper in one inch length of one slot.)

w_i = weight of armature punchings in lb. per in. length of core per slot.

Mathematical consideration of the interchange of heat between the two component bodies c and i leads to two simultaneous linear equations of the first order:

$$A\frac{d\,T_i}{d\,t} + (B + C)\,T_i - B\,T_c - C\,T_a - W_i = 0 \qquad (1)$$

$$D\frac{d\,T_c}{d\,t} + B\,T_c - B\,T_i - W_c = 0 \qquad (2)$$

where A, B, C, D are constants (see Appendix).

Since railway motors are now usually rated on the basis of the temperature rise of the windings as measured by increase in resistance we are only interested in the copper temperature T_c. Eliminating T_i from the above equations we obtain a second order equation in T_c:

$$L\frac{d^2\,T_c}{d\,t^2} + M\frac{d\,T_c}{d\,t} + N\,T_c = K' \qquad (3)$$

where L, M, N, K' are constants.

The solution of this equation is of the form

$$T_c = C_1\,e^{-\lambda_1 t} + C_2\,e^{-\lambda_2 t} + \frac{K'}{N} \qquad (4)$$

where C_1 and C_2 are constants of integration and $-\lambda_1$ and $-\lambda_2$ are roots of the equation $L\,D^2 + M\,D + N = 0$. Introducing the original constants into equation (**4**) and making certain simplifying approximations, the temperature rise of the armature copper at any time t is given by the following set of equations:

$$\theta_c = T_k\,(1 - e^{-\lambda_1 t}) + C_2\,(e^{-\lambda_2 t} - e^{-\lambda_1 t}) \qquad (5)$$

where:

$$C_2 = \frac{w_c\,S_c\,W_i - w_i\,S_i\,W_c}{(2\,w_c\,S_c + w_i\,S_i)\,b\,K_1} \qquad (6)$$

$$\lambda_1 = \frac{\left(a + \frac{p}{2}\right)K_2}{\left[\left(a + \frac{p}{2}\right)\frac{K_2}{b\,K_1} + 1\right]w_c\,S_c + w_i\,S_i} \qquad (7)$$

$$\lambda_2 = \frac{b\,K_1}{w_c\,S_c} + \frac{\left(a + \frac{p}{2}\right)K_2 + b\,K_1}{w_i\,S_i} \qquad (8)$$

$$T_k = \frac{\left[\left(a + \frac{p}{2}\right)\frac{K_2}{b\,K_1} + 1\right]W_c + W_i}{\left(a + \frac{p}{2}\right)K_2} \qquad (9)$$

θ_c is the temperature rise of the armature copper above the mean temperature of the ventilating air at time t. Since the ventilating air temperature varies quite considerably, it cannot be conveniently considered as a constant over the period of time under consideration, so that some means is necessary to take its variation into account. The following empirical relation is found to be a close approximation in modern self-ventilated motors for peripheral speeds not less than 1,000 ft. per min.:

$$\theta_a = T_k\left(\frac{700}{v_s + 1000}\right)\left(1 - e^{-\frac{v_s^3 t}{2\times10^{10}}}\right) \qquad (10)$$

Introducing this into equation (**5**)

$$\theta = T_k\,(1 - e^{-\lambda_1 t}) + C_2\,(e^{-\lambda_2 t} - e^{-\lambda_1 t}) + T_k\left(\frac{700}{v_s + 1000}\right)\left(1 - e^{-\frac{v_s^3 t}{2\times10^{10}}}\right) \qquad (5a)$$

The correction for rise in ventilating air represented by equation (**10**) is only approximate and can, of course, be made more exactly by the introduction of a more complicated expression. The rise in ventilating air temperature, however, is relatively small in comparison with the copper rise so that a correction of the above type is close enough for most applications. In all the foregoing, the mean temperature of the ventilating air is taken as the arithmetic mean between the temperature of the ingoing and outgoing air so that θ_a actually will be one-half the temperature rise of the ventilating air through the motor.

In equation (**9**), T_k is the temperature rise of the copper above the mean temperature of the ventilating air when t is infinite, that is, after a continuous run under the load condition represented by the losses W_c and W_i. Equation (**9**), therefore, gives us a means of arriving at values of K_2, by substitution of data from actual temperature tests into the equation, for various conditions of speed and ventilation. By taking a number of temperature runs on each of a wide range of motors of varying size it was possible, from equation (**9**), to find a relation between K_2 and the peripheral speed of the armature or other condition affecting the rate of heat dissipation. Fig. 3 shows the values of K_2 so obtained for a range of self-ventilated motors varying in size from 50 hp. to 310 hp., plotted against the armature peripheral speed. In these calculations and in all subsequent calculations, the quantity W_c was taken as the $I^2\,R$ loss calculated from conductor resistance plus the eddy current loss in the conductors as calculated by Field's method. As the tests from which these points are taken were ordinary test floor runs in which no special precautions for absolute accuracy were taken as would be the case in laboratory tests, the points are very favorably consistent for a curve of this type. The temperature rise by resistance was measured by taking a four point cooling curve immediately after shutting down the motor and projecting the curve back to the shutdown point. By measuring V, the rate of air flow through the motor in forced ventilated machines and, in the case of self-ventilated motors, estimating it from the losses and air rise for each test, and assuming that the axial velocity of the air over the armature surface is approximately $\frac{V^*}{0.3\,D^2}$, the velocity of the air relative to the armature surface will be, approximately, $\sqrt{v_a^2 + \left(\frac{V}{0.3\,D^2}\right)^2}$. Fig. 4 shows K_2 plotted against this relative velocity for a range of motors including both self and forced ventilated machines varying in size from 50 hp. to 800 hp. and in armature diameter from 11 to 30 in. With the aid of the curves of Figs. 3 and 4, the temperature rise above the mean ventilating air temperature after a continuous run can be predetermined from equation (**9**). However, equation (**9**) can be modified to correct for the rise in ventilating air temperature. For the line of self-ventilated motors mentioned above, this is done by adding the right hand member of equation (**10**) when t is infinite:

$$\theta_k = \left(\frac{\left[\left(a+\frac{p}{2}\right)\frac{K_2}{b\,K_1}+1\right]W_c + W_i}{\left(a+\frac{p}{2}\right)K_2} \right) \times \left(1+\frac{700}{v_a+1000}\right) \qquad \textbf{(9a)}$$

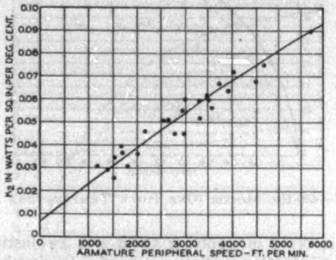

FIG. 3—K_2 FOR SELF-VENTILATED RAILWAY MOTORS

In determining the curves shown in Figs. 3 and 4 the value of κ, the conductivity of the insulation between the copper and the walls of the slot, was taken as 0.0025 watts per in. per deg. cent. This corresponds to an average value for the combination of mica, paper and varnish which is used for armature coil insulation. The temperature rise of the copper as will be seen by an inspection of equation (**9**) is considerably influenced by the value of K_1, the rate of heat transfer through this insulation; so that, considering the possibility of variations in the conductivity due to air pockets and incomplete drying out of compound, it is probable that the variations from the curve of the points of Figs. 3 and 4 can, to some extent, be ascribed to variations in the condition of the insulation.

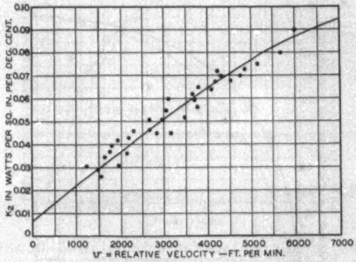

FIG. 4—K_2 FOR BOTH SELF- AND FORCED-VENTILATED RAILWAY MOTORS

The right-hand side of equation (**5**), from which time-temperature curves of a motor armature can be calculated, consists of two parts, $T_k\,(1 - e^{-\lambda_1 t})$ and $C_2\,(e^{-\lambda_2 t} - e^{-\lambda_1 t})$. The equation was arranged in this form because it illustrates clearly how the time-temperature characteristics vary from the usually accepted simple logarithmic function which the first of these two expressions represents. The second expression, $C_2\,(e^{-\lambda_2 t} - e^{-\lambda_1 t})$, is very small compared with the first when t is greater than $\frac{1}{\lambda_1}$ and disappears when t becomes infinite so that for finding the temperature rise over intervals of time exceeding the usually accepted thermal time constant, the second expression can be neglected. The equation then assumes the familiar form:

$$\theta_c = T_k\,(1 - e^{-\lambda_1 t}) \qquad \textbf{(11)}$$

For short time intervals, however, this second expression becomes very important and cannot be neglected. Figs. 5 to 10 show several time-temperature curves which were calculated by means of equation (**5**) for three motors, one a forced-ventilated motor of 450 hp. and the others, self-ventilated motors rated at 100 hp. and 50 hp. respectively. These curves were calculated for the same load and speed at which some actual temperature test giving consistent results was taken. The points plotted on the diagrams show the actual temperature rise above the mean ventilating air temperature obtained in the corresponding temperature run.

---

*Where D is armature diameter in inches.

It is recognized that a simple logarithmic curve of the form $\theta = T_k\,(1 - e^{-\lambda_1 t})$, involving a single thermal time constant, could be found which would pass through any such set of two, or even more, test points. But it has been found very difficult to discover a sufficiently simple law which would connect the constants obtained experimentally of such an expression with the main design dimensions of a wide range of armature sizes. It has been shown that the equations (**5**) to (**9**) can be made, with the aid of a curve or set of curves of the type shown in Figs. 3 and 4, to represent within a reasonable degree of accuracy, the thermal characteristics of a very wide range of machines. The only feature which such a group of motors need have in common is that the path of the cooling air through the motor should be essentially similar in all machines of the group. The chief purpose of this method is the predetermination of the thermal characteristics of a projected motor design when only preliminary data are available. The method may appear unwieldy at first sight but with a little practise these equations can be handled quite easily and the extra time and labor involved in applying them will be justified in most cases by the smaller margin of safety with which it will be found that a new design of motor can be applied.

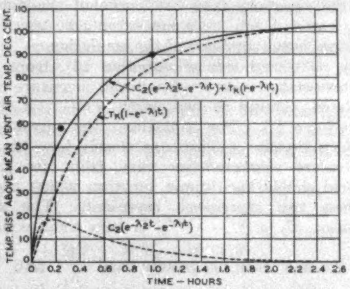

FIG. 5—450-HP. MOTOR (ONE HOUR TEMPERATURE RUN)

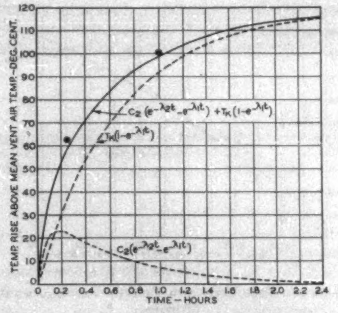

FIG. 6—450-HP. MOTOR (ONE HOUR TEMPERATURE RUN)

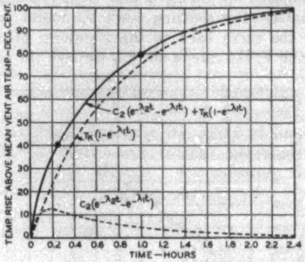

FIG. 7—450-HP. MOTOR (ONE HOUR TEMPERATURE RUN)

APPENDIX

Since the flow of heat through the insulation at the top of the slot is neglected, all the heat escaping from the copper will be transferred to the iron. Considering only one inch length of core, the rate of heat flow through the insulating wall will be $b\,K_1$ watts per deg. cent. Referring now to Fig. 2, the heat increment in time $d\,t$ in the body i will be:

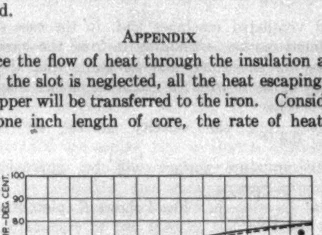

FIG. 8—450-HP. MOTOR (CONTINUOUS TEMPERATURE RUN)

$$W_i\,d\,t + (T_c - T_i)\,b\,K_1\,d\,t \qquad \textbf{(12)}$$

The heat stored in time $d\,t$ will be

$$w_i\,S_i\,d\,T_i \qquad \textbf{(13)}$$

The heat imparted to the ventilating air will be

$$\left[a\, K_2 (T_i - T_a) + p \frac{K_2}{2} (T_i - T_a) \right] d\,t \qquad (14)$$

Equating these values and rearranging:

$$w_i\, S_i \frac{d\,T_i}{d\,t} + \left[b\, K_1 + \left(a + \frac{p}{2} \right) K_2 \right] T_i$$

$$- b\, K_1\, T_c - \left(a + \frac{p}{2} \right) K_2\, T_a - W_i = 0 \qquad (15)$$

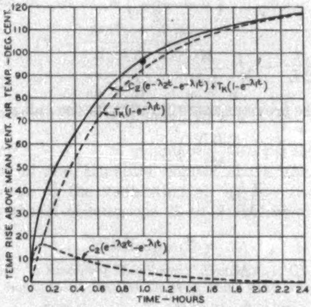

Fig. 9—100-Hp. Motor (One Hour Temperature Run)

In the body *c*, the heat increment will be:

$$W_c\, d\,t$$

The heat transferred to the body *i* will be:

$$b\, K_1 (T_c - T_i)\, d\,t \qquad (16)$$

The heat stored will be:

$$w_c\, S_c\, d\, T_c \qquad (17)$$

Equating these quantities and rearranging

$$w_c\, S_c \frac{d\,T_c}{d\,t} + b\, K_1\, T_c - b\, K_1\, T_i - W_c = 0 \qquad (18)$$

Let

$$w_i\, S_i = A$$

$$b\, K_1 = B$$

$$\left(a + \frac{p}{2} \right) K_2 = C$$

$$w_c\, S_c = D$$

Then we have:

$$A \frac{d\,T_i}{d\,t} + (B + C)\, T_i - B\, T_c - C\, T_a - W_i = 0 \qquad (15a)$$

$$D \frac{d\,T_c}{d\,t} + B\, T_c - B\, T_i - W_c = 0 \qquad (18a)$$

From (18a) we have:

$$T_i = \frac{D}{B} \frac{d\,T_c}{d\,t} + T_c - \frac{W_c}{B} \qquad (19)$$

Differentiating (18a) with respect to *t*:

$$D \frac{d^2\,T_c}{d\,t^2} + B \frac{d\,T_c}{d\,t} - B \frac{d\,T_i}{d\,t} = 0$$

or

$$\frac{d\,T_i}{d\,t} = \frac{D}{B} \frac{d^2\,T_c}{d\,t^2} + \frac{d\,T_c}{d\,t} \qquad (20)$$

Substituting these values for T_i and $\frac{d\,T_i}{d\,t}$ in equation (15a) and rearranging

$$A\, D \frac{d^2\,T_c}{d\,t^2} + [A\, B + (B + C)\, D] \frac{d\,T_c}{d\,t}$$

$$+ B\, C\, T_c - B\, C\, T_a - (B + C)\, W_c - B\, W_i = 0 \qquad (21)$$

Let

$$A\, D = L$$

$$A\, B + (B + C)\, D = M$$

$$B\, C = N$$

$$B\, C\, T_a + (B + C)\, W_c + B\, W_i = K'$$

Equation (21) becomes:

$$L \frac{d^2\,T_c}{d\,t^2} + M \frac{d\,T_c}{d\,t} + N\, T_c = K' \qquad (21a)$$

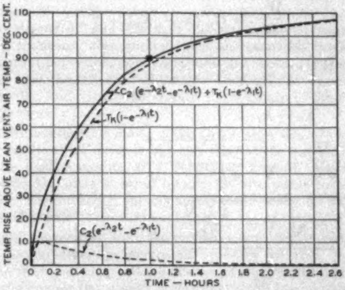

Fig. 10—50-Hp. Motor (One Hour Temperature Run)

The solution of this equation is:

$$T_c = C_1\, e^{-\lambda_1 t} + C_2\, e^{-\lambda_2 t} + \frac{K'}{N} \qquad (22)$$

Where:

$$\lambda_1 = \frac{M}{2\,L} - \sqrt{\frac{M^2}{4\,L^2} - \frac{N}{L}} \qquad (23)$$

$$\lambda_2 = \frac{M}{2\,L} + \sqrt{\frac{M^2}{4\,L^2} - \frac{N}{L}} \qquad (24)$$

$$\frac{K'}{N} = T_a + \frac{(B + C)\, W_c + B\, W_i}{B\, C}$$

Substituting this in equation (**22**) and calling:

$$\frac{(B+C)\,W_c + B\,W_i}{B\,C},\ T_k:$$

$$T_c - T_a = C_1\,e^{-\lambda_1 t} + C_2\,e^{-\lambda_2 t} + T_k \qquad (\mathbf{25})$$

When $t = 0,\ T_c - T_a = 0$

$$C_1 + C_2 + T_k = 0$$

or

$$C_1 = -C_2 - T_k$$

so that

$$T_c - T_a = C_2\,(e^{-\lambda_2 t} - e^{-\lambda_1 t}) + T_k\,(1 - e^{-\lambda_1 t}) \qquad (\mathbf{26})$$

From equation (**19**), knowing that when $t = 0$,

$$T_c = T_i = T_a:$$

$$T_a = \frac{D}{B}\,\frac{d\,T_c}{d\,t} + T_a - \frac{W_c}{B}$$

or

$$\frac{D}{B}\,\frac{d\,T_c}{d\,t} = \frac{W_c}{B} \qquad (\mathbf{27})$$

Differentiating equation (**26**) with respect to t:

$$\frac{d\,T_c}{d\,t} = C_2\,(\lambda_1\,e^{-\lambda_1 t} - \lambda_2\,e^{-\lambda_2 t}) + T_k\,\lambda_1\,e^{-\lambda_1 t}$$

Putting $t = 0$ and $\frac{d\,T_c}{d\,t} = \frac{W_c}{D}$ (from equation (**27**):

$$\frac{W_c}{D} = C_2\,(\lambda_1 - \lambda_2) + T_k\,\lambda_1$$

or

$$C_2 = \frac{\frac{W_c}{D} - T_k\,\lambda_1}{\lambda_1 - \lambda_2} \qquad (\mathbf{28})$$

$$\lambda_1 = \frac{M}{2\,L} - \sqrt{\frac{M^2}{4\,L^2} - \frac{N}{L}}$$

$$= \frac{1 - \sqrt{1 - \frac{4\,L\,N}{M^2}}}{\frac{2\,L}{M}}$$

$$\frac{1 - \left(1 - \frac{2\,L\,N}{M^2}\right)}{\frac{2\,L}{M}}$$ (approx.) since $\frac{4\,L\,N}{M^2}$ is of the order of 0.2

$$= \frac{N}{M}$$

$$= \frac{B\,C}{A\,B + D\,(B+C)}$$

$$= \frac{b\,K_1\left(a + \frac{p}{2}\right)K_2}{w_i\,S_i\,b\,K_1 + \left[\,b\,K_1 + \left(a + \frac{p}{2}\right)K_2\right]\,w_c\,S_c}$$

$$= \frac{\left(a + \frac{p}{2}\right)K_2}{\left[1 + \left(a + \frac{p}{2}\right)\frac{K_2}{b\,K_1}\right]w_c\,S_c + w_i\,S_i} \qquad (\mathbf{7})$$

$$T_k = \frac{(B+C)\,W_c + B\,W_i}{B\,C}$$

$$= \frac{\left[1 + \left(a + \frac{p}{2}\right)\frac{K_2}{b\,K_1}\right]W_c + W_i}{\left(a + \frac{p}{2}\right)K_2} \qquad (\mathbf{9})$$

$$\lambda_2 = \frac{M}{2\,L} + \sqrt{\frac{M^2}{4\,L^2} - \frac{N}{L}}$$

Using the previous approximation for the radical:

$$\lambda_2 = \frac{1 + \left(1 - \frac{2\,L\,N}{M^2}\right)}{\frac{2\,L}{M}}$$

$$= \frac{M}{L} - \frac{N}{M}$$

$$= \frac{A\,B + D\,(B+C)}{A\,D} - \frac{B\,C}{A\,B + D\,(B+C)}$$

Neglecting the last term which is very small in comparison with the first:

$$\lambda_2 = \frac{B}{D} + \frac{B+C}{A}$$

$$= \frac{b\,K_1}{w_c\,S_c} + \frac{b\,K_1 + \left(a + \frac{p}{2}\right)K_2}{w_i\,S_i}$$

$$C_2 = \frac{\frac{W_c}{D} - T_k\,\lambda_1}{\lambda_1 - \lambda_2}$$

$$\lambda_1 - \lambda_2 = -2\sqrt{\frac{M^2}{4\,L^2} - \frac{N}{L}}$$

$$= -\frac{M}{L}\sqrt{1 - \frac{4\,L\,N}{M^2}} = -\frac{M}{L}\left(1 - \frac{2\,L\,N}{M^2}\right) \text{ approx.}$$

$$= \frac{2\,B\,C}{A\,B + D\,(B+C)} - \frac{A\,B + D\,(B+C)}{A\,D}$$

$$T_k\,\lambda_1 = \frac{N}{M}\;\frac{(B+C)\,W_c + B\,W_i}{N}$$

$$= \frac{(B+C)\,W_c + B\,W_i}{M}$$

$$\therefore C_2 = \frac{\dfrac{W_c}{D} - \dfrac{(B+C)\,W_c + B\,W_i}{M}}{\dfrac{2\,B\,C}{A\,B + D\,(B+C)} - \dfrac{A\,B + D\,(B+C)}{A\,D}}$$

$$= -\frac{\dfrac{A\,B}{D}\,W_c - B\,W_i}{\dfrac{A\,B^2}{D} + \dfrac{D}{A}\,(B+C)^2 + 2\,B^2}$$

Putting $(B + C)^2 = 2\,B^2$, dividing through by B^2 and neglecting D^2

$$C_2 = \frac{D\,W_i - A\,W_c}{B\,(A + 2\,D)}$$

$$= \frac{w_c\,S_c\,W_i - w_i\,S_i\,W_c}{(2\,w_c\,S_c + w_i\,S_i)\;b\,K_1} \qquad \textbf{(6)}$$

Putting $T_c - T_a = \theta_c$ in equation (**26**), the temperature rise of the armature copper above the mean temperature of the ventilating air at any time t is given by the set of equations (**5**) to (**9**) inclusive.

Discussion

John Basta: We know how difficult it is to obtain a simple method of calculation of heating curves on assumptions following closely the experience. With those machines where the exchange of heat from winding to air cannot be neglected, the heating curve differs widely from a simple exponential curve. However, Mr. Lightband found it justified to neglect the exchange mentioned with armatures of railway motors and succeeded in showing that the heating curve for them is composed from two exponential curves. The actual heat runs used for verifying the calculated curves, however, do not give more than two, and in some cases even one point only. That is why we would suggest to Mr. Lightband that he undertake another series of tests in which complete curves would be obtained. This, of course, should not be done by measuring the resistances of armature windings, as in the tests presented, but rather by placing temperature detectors into the winding, which would be connected through slip rings to meters. With such an arrangement, the distribution of temperatures along the winding could be ascertained at the same time.

Carl J. Fechheimer: It has been recognized for several years that the usual transient equation for temperature in an armature in which there is one time constant is inadequate, particularly during the first part of the period after the load on the machine is changed. The thermal time constant is given by the ratio of the energy stored to the power dissipated, and that ratio is usually considerably different for the copper and the iron. The errors that may arise for short time ratings, if only one time constant is considered, may be of considerable magnitude. Mr. Lightband has brought out these points clearly.

The general forms of the transient equations when two bodies are considered are analogous to those of the two electric circuits which are magnetically coupled, and when self and mutual inductances are considered. In either case, it is essential to solve two differential equations simultaneously. The solutions for the thermal circuit may be obtained by making use of the principles of superposition and reciprocity. The solutions obtained thereby are perhaps somewhat more general than the forms obtained by Mr. Lightband.

Mr. Lightband's solutions are for the heating state, but they might easily be extended to the cooling state. When the cooling curve is plotted, it is found that the initial part is similar to the "sub-transient" for the decay of current in a suddenly short-circuited alternator, and like it, it dies out relatively soon, and only the "transient" state then obtains, and then only the second time constant is needed. Mr. Lightband has shown for the heating curve that the influence of the first time constant diminishes fairly rapidly, and subsequently only the influence of the second is of importance.

The third assumption made in the paper, that the rate of heat transfer in the axial ducts is one-half that at the outer surface, limits the final equations to a particular type of ventilation. This should be borne in mind by anyone who plans to use the equations. Undoubtedly, the equations could easily be modified so as to make them of more general form.

It should be recalled that the problems involved in heat flow become too involved to secure an accurate solution. For example, in many machines the influence of the longitudinal heat flow in the copper has a very large effect upon the copper temperature. While the differential equations for this case can be written, the solutions for the transient state become too involved to admit of placing them in practical form. It is essential to make assumptions such as Mr. Lightband has done, although his assumptions may not be the ones to adopt for some other class of apparatus. Thus, his results are all based upon the average copper temperature as measured by resistance. For machines having long cores, the copper at the middle is usually at considerably higher temperature than the average, and consequently his assumption *B* would introduce too large an error.

P. H. Powell: A point which is not quite clear in Mr. Lightband's paper is the definition of K_2 and the surface of the armature regarded as radiating. His argument seems to be based on the assumption that all the heat is dissipated by the surfaces of the tops of the teeth and by the surface of the ventilating ducts; on the other hand, K_2 is defined with respect to the armature surface again somewhat indefinitely. If one regards the outside barrel surface of the armature (circumference multiplied by overall length) as being the only radiating surface, the value of K_2 for a speed of 3,000 feet per minute is about 0.1 for open type machines. If one adds up the external barrel surface, the internal barrel surface, and the ducts, the figure for K_2 appears to be about 0.04. Mr. Lightband's result seems to indicate a figure of about 0.05.

There are, of course, differences in types and in ventilating arrangements that make a comparison almost impossible, but it would seem that if only the tops of the teeth and the iron surface of the ventilating ducts are allowed as radiating surface, the figure for K_2 should be considerably higher than 0.05. However, it is very interesting to find a method involved which will enable the short-time rating to be better defined.

D. A. Lightband: It is pointed out that in machines where direct flow of heat from the winding to the air cannot be neglected, the heating curve differs widely from a simple exponential curve. I have shown that in railway motors, even though this heat flow is neglected, there will still be considerable deviation from the simple exponential curve. Attention has been drawn by Mr. Basta to the use of only two test points as an illustration of the closeness of the method. It should be pointed out that the two points are really three, since the origin must be included. Any kind of exponential curve cannot be drawn through three such points, which would represent a reasonable characteristic heating curve of a motor. Even a simple exponential curve drawn through these three points has been found to differ very widely from an exponential heating curve estimated from the one hour and continuous temperature tests.

The suggestion by Mr. Basta that test curves be taken by temperature detectors in the winding rather than by measuring the temperature rise by the resistance method would be rather defeating the object of this method since it is on temperature rises measured by resistance that the ratings of all modern railway motors are based. Measurement of distribution of temperature along the winding longitudinally is beyond the scope of this paper.

Mr. Fechheimer mentions the fact that the solutions are for the heating state only. In the consideration of cooling, it should be pointed out that if the different time constants in the copper and iron are to be taken into account, a knowledge is necessary of the exact nature of the heating immediately prior to the commencement of the cooling curve. This is necessary because the nature of the cooling curve will depend on the initial relation between the temperature rise of the iron and that of the copper. The following equations will give the cooling curve when both the initial temperature rise of the copper and of the iron are known.

Equation for cooling with no power on:

$$\theta_c = \theta_o e^{-\lambda_1 t} + C_4 \left(e^{-\lambda_2 t} - e^{-\lambda_1 t}\right) \qquad \text{(c)}$$

where θ_o = initial copper temperature

λ_1 and λ_2 defined by equations (7) and (8)

$$C_4 = \frac{(w_i S_i + w_c S_c)(\theta_o - \theta_i) - w_c S_c \left(a + \frac{p}{2}\right) \frac{K_2}{b K_1} \theta_i}{w_c S_c + 2 w_i S_i} \qquad \text{(e)}$$

θ_i = initial iron temperature

For cooling with power on:

$$\begin{aligned} \theta_c &= T_k \left(1 - e^{-\lambda_1 t}\right) + C_3 \left(e^{-\lambda_2 t} - e^{-\lambda_1 t}\right) + \theta_4\, e^{-\lambda_1 t} + C_4 \left(e^{-\lambda_2 t} - e^{-\lambda_1 t}\right) \\ &= T_k + (\theta_o - T_k)\, e^{-\lambda_1 t} + (C_3 + C_4) \left(e^{-\lambda_2 t} - e^{-\lambda_1 t}\right) \qquad \text{(f)} \end{aligned}$$

Mr. Powell has brought up the point that my definition of K_2 is somewhat indefinite since I do not specifically state whether it is based on the heat radiating from the whole external and internal radiating surface of the armature. He is of the opinion that if this constant refers to the radiating surface obtained by adding up the external surface of the armature core and winding, the internal surface of the armature coils, and the surface of the ducts, it should have a value higher than that given in the paper.

I have made the definition of K_2 as the coefficient of heat transfer from the armature surface to the ventilating air. By "armature surface" is meant the external surface of the armature core and the internal surface of the ventilating ducts. Since I have assumed that no heat flow has taken place from the armature core to the windings in a longitudinal direction, it is quite unnecessary to include the outer surface of the windings as part of the radiating surface. The amount of heat which flows through the insulation at the mouth of the slots is a very small proportion of the total heat flow from the armature and has been neglected, and therefore the only radiating surfaces which need be considered are the tops of the teeth and the ventilating ducts.

The figures for K_2 which are calculated from temperature tests by means of the equations given in the paper and shown in Figs. 3 and 4, correspond very closely to values of rate of heat transfer for various kinds of rotors given in Luke's paper referred to in the bibliography. Luke's results were obtained by means of an exhaustive series of experiments and offer a very sound basis of comparison for heat transfer constants in rotating armatures.

High Capacity Rectifier Efficiency Improves by Sectionalizing

By A. L. ATHERTON*

Member, A.I.E.E.

Synopsis.—The reasons for adopting the sectional construction are given and discussed at some length. The new features of design and construction which make the sectional arrangement feasible are described. One arrangement of sections into a unit is described and alternative arrangements are discussed briefly.

Performance characteristics are described in broad terms and the extent of the improvement over previous type is pointed out.

A forecast of future development is indicated.

THE idea of the sectional type mercury arc rectifier is based on the obvious, but apparently heretofore unrecognized, fact that the best possibilities inherent in the principle are realized only in the smaller sizes. Efficiency, reliability, economy, and flexibility of both application and use are all far better in small than in large units. The advantages appear to be fundamental and, therefore, permanent.

The rectifier is not alone in this. Many familiar things are inherently at their best in small sizes. The established and common "unit type" things are so well known that we have come to overlook the limitations and inefficiencies introduced by the subdivision and to accept the scheme as natural and right. In suspension insulator units, a large part of the insulation material is shunted by metal, assembly operations are duplicated many times in a single unit of use, and the distribution of potential along the string is wrong unless corrected; but the mechanical strength, flexibility, adaptability to all voltages, and the economy of concentrating manufacture and stocks in a single size of unit are so much more important that the disadvantages almost vanish. Because the benefits outweighed the disadvantages, the introduction of the idea of sectionalization in line insulators created a new utility, and because the increase in utility was great, the whole of the associated art of long distance transmission received a major stimulus.

So with the metal tank mercury arc rectifier. Subdivision into unit sections introduces both advantages and disadvantages, but the advantages so far outweigh the disadvantages that, once the conception is seriously considered and the sectional design actually worked out, doubts disappear and it seems the right and natural way to proceed.

Development through the past twenty-nine years has resulted in rectifiers of small capacity, 500 kw. for example, with a high degree of reliability, a reasonable cost, and an efficiency which makes available for the higher voltage conversion applications the unique quietness and freedom from mechanical wear which has provided the major incentive throughout the development. When size is increased to get larger output capacity, however, the quality decreases markedly. Reliability decreases not only in proportion to size as might be expected, but more rapidly, because the complexity of the problem of control of the hurricane flow of vapor from the cathode is increased many fold when size is even doubled. The "outage time" per year with 3,000-kw. rectifiers is several times as great as with 500-kw. units. Cost per unit of output does not decrease with increase of size, as it does with some apparatus, because manufacturing problems increase faster than in proportion to size, and because the total requirement for this kind of equipment, with capabilities and limitations as they are even in the smaller sizes, will not support organized "line manufacture" for the larger capacities. Efficiency falls off with increase in size because of the longer arc and greater exposure to deionizing surfaces, and because the fundamentally less reliability makes necessary an increase in loss producing devices to get acceptable quality. With present designs, the internal losses for a 500-kw. unit are approximately 25 per cent less than for a 3,000-kw. unit, both based on 600-volt operation.

The major disadvantages which go with size appear to be fundamental and permanent, whatever advances may be made in the art. Larger units will always be less efficient, and the reliability and cost disadvantages will probably persist.

If we think of multiple installations of conventional small capacity units of the sort which have been available in the past, we realize that the project is impracticable. The space required is too great and the multiplicity of control and protective devices appears questionable. But when we think of subdivision of a large capacity, taking advantage of space economies resulting from recent advances in the art, building the structure in sections but installing, controlling, protecting and using it as a whole, the project becomes feasible and the desirable qualities of the small rectifier are made available for the larger capacities while the disadvantages of sectionalizing are so reduced as to become negligible.

Our work with rectifiers of conventional size and characteristics has resulted in the conviction that the limitation in capacity for a given design, as for example

---

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

the 500-kw. unit shown in Figs. 1 and 2, lies in local limitations of the various parts, for example, the limits of conductivity and heating at the anode, and not in the perhaps more fundamental and difficult tendency to arc back at the higher currents. Such a unit carries a nominal current of 833 amperes continuously, 1,250 amperes for two hours, and 2,500 amperes for one minute. In all our testing, which includes use at currents up to 17,000 amperes on short circuit, and which includes considerable experimental experience of loads of 2,000 to 2,500 amperes for periods of 5 to 30 minutes, dependent on temperature rise, we have not experienced arcing back as a limitation. Extended service experience with a limited number of installations gives the same result. Evidently, change in the details, leaving the general arrangement unaltered, would make it possible materially to reduce the size of the containing tank without affecting the ability of the unit to carry the loads required by its rating. Experiments along these lines have verified this conclusion.

FIG. 4—SECTION SHOWING ARRANGEMENT OF PARTS OF UNIT SHOWN IN FIG. 3

The diameter is 54 inches and the overall height is 41½ inches. The kw. rating per unit volume is thus over 3 times as great as for the conventional unit

As a further step, a rearrangement of parts made possible a still further reduction in size for a given rating, and at the same time brought about some reduction in the internal losses. The rearrangement was based on the knowledge gained in our experimental experience as to the effect of the way the vapor flows from the cathode to the condensing wall and the position of the anode structures in relation to this stream of ionized vapor on the limiting current of which the rectifier unit is capable, without excessive arcing back. Although the whole mechanism of vapor flow and its effect on arcing back are obscure as yet, several factors which influence performance have been established. The design shown in Figs. 3 and 4 is an attempt to take these as yet rather intangible and, it must be admitted, somewhat uncertain factors into account in the most satisfactory way possible at the present time.

The anode support and shielding arrangement also offered an opportunity for progress and a rather extended series of experiments resulted finally in the anode structure shown. Processing to eliminate foreign material and keep the gas evolution under operation at as low a value as possible, have progressed along with the design development.

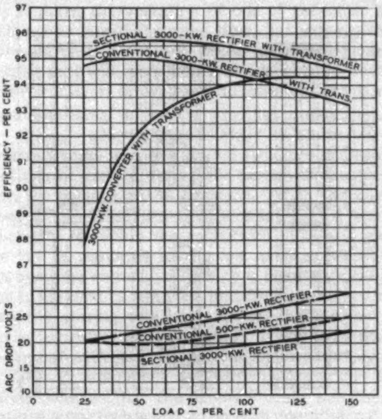

Fig. 5—Representative Arc Drop and Efficiency Curves for Conventional and Sectional Rectifiers

As a result of these improvements, the rectifier section shown in Figs. 3 and 4 is capable, with a reasonable margin, of a standard nominal rating of 750 kw. at 600 volts, and even of higher short-time overloads as sometimes required.

This section, at 750-kw., 600-volt rating, is required to carry a normal current of 1,250 amperes, with 50 per cent overload, or 1,875 amperes for two hours. Owing to the fact that final temperatures are reached in times of the order of two hours, it is felt that the two-hour capacity can best be indicated by continuous operation at the 50 per cent overload value and our experimental tests have been made in this way, thus including in a single test some margin of safety along with a degree of acceleration of the test. Double load, or 2,500 amperes is required by standard nominal rating for a period of one minute following full load. Experimental tests have been made at this current up to 5 minutes duration.

Fig. 6—Sectional Rectifier, 3,000-Kw., 600-Volt Rating

This unit consists of four sections each of 750-kw. rating, the supporting structure and the necessary auxiliary equipment for maintaining the vacuum and dividing the load. Some control and protective devices are also conveniently mounted on the structure

Fig. 7—View of Rear of 3,000-Kw., 600-Volt Sectional Rectifier Showing the Arrangement of the System for Maintaining the Vacuum

In all these operations, arcing back is very infrequent if it occurs at all and it is a requirement that the rectifier can be put into operation again immediately following such an occurrence.

The internal losses in the rectifier are determined by the arc drop, or voltage from anode to cathode during the conducting period. This value varies with load current and can be indicated by a curve of voltage drop against load current. The value that determines efficiency is the average for the various anodes. Fig. 5 shows average arc drop curve for the unit indicated by Figs. 3 and 4. The dotted curve shows the value for the older, conventional, unit shown by Figs. 1 and 2. As the size of a rectifier is increased, the arc path becomes longer and losses per kw. output become greater. Experimental rectifiers of 3,000 kw. with a single tank have had arc drop values as shown by the dot and dash curve of Fig. 5. It is seen that at full loads the difference between these experimental single tank 3,000-kw. rectifiers and the section shown in Figs. 3 and 4 amounts at full load to approximately 6 volts or 1 per cent, on the basis of 600 volts output. With ordinary load factors and rates for power, this difference in 3,000-kw. rating saves from $600 to $1,500 per year power cost, which represents an added value of from $4,000 to $10,000.

The proportions of the new units are such as to make it feasible to mount them in service one above another. Thus, a 3,000-kw. unit can be made of four 750-kw. sections mounted two side by side and two deep. Such an arrangement is shown in Fig. 6. The floor space required for such an assembly is approximately 118 inches wide, by 68 inches deep over all parts, including auxiliary equipment. The over-all height is 113 inches, and the ceiling height of the room necessary to accommodate this equipment need not exceed this value except for electrical clearance of a few inches and whatever may be necessary to provide for adequate working space certainly not more than two feet. It is evident that there is a considerable space economy.

Such an arrangement is likely to prove the most convenient for usual applications. There is no reason, however, why other arrangements cannot be used where available space places a limitation on one or more dimensions. For example, the auxiliary equipment and wiring can be arranged between the units at the center, at some penalty from the standpoint of accessibility, making the floor dimensions approximately 150 by 55 inches. Or the four units may be mounted in a single column with floor dimensions of about 65 by 70 and a height of 210 inches. Or the parts may be separated in two or groups, possibly at some expense in auxiliary equipment.

The problem of paralleling is the same as in the case of a single tank rectifier using the same number of anodes and, except in detail, is the same as for any rectifier using twelve or more anodes. Load balancing is inherently approximately correct owing to the fact that the voltage across the arc rises with increasing current after a minimum at about 40 per cent load is passed. To get a closer balance, anode balancing coils are used and these are so arranged as to introduce no appreciable impedance into the circuit under normal operation. In the event that it is desired to take a section out of service, for maintenance or any other reason, the corresponding balancing coil sections are short circuited by connection links provided for the purpose.

One arrangement of vacuum pumping is indicated in Fig. 7. Use is made of two independent pumping systems, connected through manifolding to the various

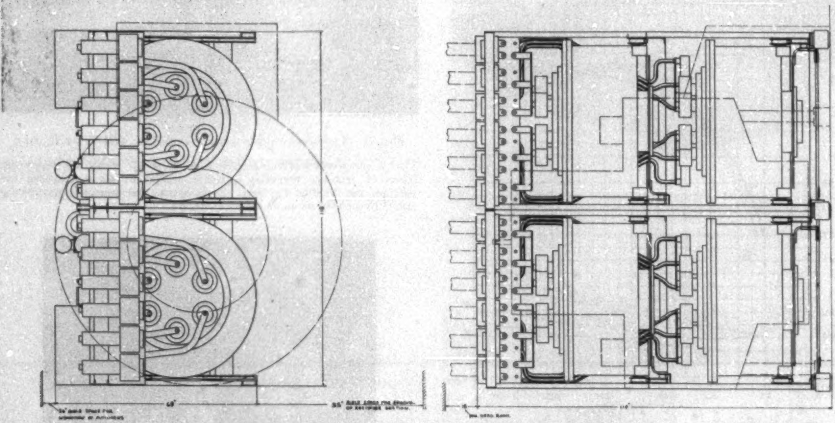

FIG. 8—OUTLINE OF 3,000-KW., 600-VOLT SECTIONAL RECTIFIER

Approximate dimensions of an experimental single tank unit are indicated by the dot and dash outline sections and with cross connections so arranged as to permit the use of either pumping system on any or all of the tanks. The various sections of the rectifier are connected to the vacuum manifold through two valves of unique design, provided with a sealing plate as an extra precaution against outside air. Even if such a valve should develop a leak, this safeguard would prevent any leakage into the tanks except at a very slow rate and for the minute or less while the valve position is being changed. The use of two valves permits the separation of a single section from the balance of the structure without admitting air to either part. In the event that maintenance work is required, it is thus possible to put the repaired section in condition by pretreatment, then install it and by proper manipulation of the valves, exhaust it completely without admitting air to either that unit or any part of the operating system. With the pumping arrangement shown, this requires the operation of one of the other units with valves closed for some time, but experience has indicated that if properly made and treated out the rectifier unit will carry normal loads without pumping for several hours or even several days without damage.

Sectionalizing inherently provides the utility that any damage which occurs is likely to be limited to a relatively small part of the total structure and that the load can be carried during the period of maintenance with the balance of the structure. With the arrangement in Fig. 7, a faulty section is segregated from the others by removing the connection links and closing the valves, requiring only a few minutes, before load can again be carried. Although a maintenance operation is required to remove a unit from the structure for repairs requiring two hours or so, this can be done during a light or no load period. It would be possible to arrange with jack connections and separate systems of auxiliary equipment or flexible pumping and water connections, so that the operator could pull the unit forward a few inches and go on with operation with the balance of the equipment after an interruption of one or two minutes. The choice between these two plans depends on the frequency with which interruptions are likely to occur. The inherent quality in the design, together with the experience thus far indicate that the interruptions requiring maintenance will be so infrequent as to make the simpler plan preferable.

The project for sectionalizing, together with the development in working out sections of suitable dimensions and proportion, thus makes available an increased degree of reliability, increased flexibility in application and use, improvement in manufacturing requirements, and an efficiency advantage of 1 per cent or more. Beyond this is the belief that as time goes on and as we acquire a clearer understanding of the fundamental knowledge gained from our research, but not yet fully used in design, further improvement will be made in respect to efficiency and size. It is to be expected that, as this progress occurs, the development will be along the lines of sectional structures rather than along the lines of single unit arrangements.

It is obvious that a development such as this is one to which essential contributions are made by many individuals. The successful completion of such a project requires a variety of knowledge, experience and talents, no part of which can safely be omitted. The author wishes to acknowledge essential contributions to this development by the research, substation, switchboard, transformer, and manufacturing engineers of the Westinghouse Electric & Manufacturing Company as well as by the design engineers whose work has made possible the design improvements. Special acknowledgment is also made of the enthusiastic and courageous support and encouragement of our executives, especially Messrs. Rugg and Kintner.

Discussion

A. W. Hull: This discussion relates to the fundamental limitation of rectifiers as given in the paper: namely, the prophecy that "the major disadvantages which go with size appear to be fundamental and permanent. Larger units will always be less efficient and probably less reliable."

The theory of rectifiers and our experience up to the present does not seem to me to justify this conclusion. The statement that "efficiency falls off with increase in size because of the longer arc" does not appear to me to apply to large rectifiers. Efficiency does not depend fundamentally on arc length but upon the ratio of length to width, or diameter, of arc path. When the dimensions of a rectifier are doubled, the width of the arc path is doubled as well as the length, and the total arc drop remains unchanged. This is in agreement with the theory of the nature of arc drop and with all experimental evidence, so far as I am aware. If large rectifiers are at the present moment less efficient than small ones, it is, I believe, a mere chance which is due to the relative state of development, and not a fundamental limitation of large rectifiers.

The same is true in regard to reliability. The only theoretical prediction regarding reliability, as a function of size, is that the arc does not tend to concentrate on a single point of a large anode but, after reaching a definite density, which is the same as the density in small rectifiers, it spreads uniformly until it covers the whole anode at full load. Hence, size does not introduce danger from concentration. There is no evidence, with which I am familiar, either theoretical or experimental that would indicate any fundamental reduction in reliability with increase in size, or the need of increased baffling in order to obtain reliability.

C. A. Butcher: It is perhaps quite generally known that I have not been an enthusiast for mercury arc power rectifiers. During eighteen years of experience having much to do with power supply for electric railways, I have witnessed many improvements in the design of substations. In that time, high reluctance commutating poles and high-speed circuit breakers solved the flashover problem in the operation of 60-cycle synchronous converters. The perfection of automatic control including supervisory, effected economies and improvement in operation.

Shortly after the first display of enthusiasm for the rectifier in America, following a lapse of a few years during which development on the part of American manufacturers ceased, I made a careful review of the available literature on the subject. This included the early development experience of my own company as well as that of one European manufacturer—also reports covering the operation and performance of a number of European rectifier installations. In a paper* I compared the rectifier with the synchronous converter. It did not appear that the conventional design of rectifier which has changed but little since then could on economic grounds replace the converter, in the 600-volt class. The demand for conversion apparatus for higher voltages is at present not of itself such as to be conducive to commercial development. The inefficiency of the rectifier at lower voltages has limited its application with few exceptions to the voltages of 600 and above. Even in the 600-volt class, it has not had the advantage of equality from the standpoint of service availability or first cost. Only at light loads is there any margin in efficiency favoring the rectifier. This advantage is very much discounted in metropolitan areas where conversion units are added to and taken out of service as demands require, which effects an average load per unit of from 75 to 100 per cent of rating.

It has not been demonstrated that the maintenance of metal tank mercury arc rectifiers will be any less than for other types of conversion apparatus.

The auxiliary equipment required with rectifiers is much greater than with synchronous converters.

On the whole, large rectifiers of the conventional type are perhaps in a class with 600-volt, 60-cycle synchronous converters before the introduction of high reluctance commutating poles and high-speed circuit breakers.

It is certain that if the rectifier is to stand as a distinct and economic advance in the art, something must be done to assure fewer service interruptions. The record established by modern synchronous converters in this respect will be difficult to equal. Also definite improvement in full load efficiency is fundamental to successful exploitation; otherwise the synchronous converter will be continued as a competitor with consequent economic loss.

Mr. Atherton has described a new development—a sectional rectifier. Tank volume per unit of capacity has been so reduced that an assembly of four 750-kw. units requires considerably less space than a single 3,000-kw. unit of conventional design. Brief as has been experience in actual service following extensive research laboratory work and testing, indications are strong that a high order of availability is to be expected. Efficiency is definitely one per cent better than that of a single tank unit of equal rating. One or more sections may be removed from service without impairing service from the remaining sections. Only a few minutes are required to disconnect a section. Division of load between sections is practically perfect. A sectionalized assembly minimizes the necessity for spare conversion equipment which is no small advantage in its favor considering capital investment in real estate, buildings, and switching equipment.

The multiplication of auxiliaries might seem a formidable objection, but surely not more so than the number of devices that go into an automatic substation. Having been intimately connected with this latter development, the success of which is unquestionable, I feel certain that there is very little cause for concern.

Truly, for the first time, I am enthusiastic about a rectifier.

W. E. Gutzwiller: The idea of the sectional type rectifier is not new. Previous to the year 1926, when 1,000 amperes was about the maximum rating per rectifier tank, sectional arrangements were used by all manufacturers wherever larger capacities were involved. Practically all rectifier installations in this country between the years 1923 and 1926 had two rectifier tanks connected to a common transformer. In Europe at about the same period as many as six tanks were operated from one transformer. Then rectifiers were usually assembled side by side on a common frame and were exhausted by a common vacuum pump set. As soon, however, as rectifiers of larger capacity had been developed sufficiently, it was found that their manufacturing cost, floor space requirements, and attendance were considerably less than for a sectional arrangement of smaller units and their reliability greater. The result was that the sectional idea was almost entirely abandoned.

The smaller sizes of rectifiers have been undergoing a process of development for a great many years, whereby certain of their features have been sufficiently perfected resulting in a slight gain in efficiency when compared with the larger sizes more recently produced. Without doubt, however, further development of the larger types will follow along similar lines so that the present slight difference in efficiency will probably disappear. Where this slight gain in efficiency is a factor of considerable commercial importance as for instance in electrolytic plants, then the sectional idea can and has been adopted.

The new feature of the rectifier described in the foregoing paper is the reduced overall height which permits at least for lower voltages, the compact assembly of a number of tanks side by side or one above the other in a cubicle form. This reduction in height is made possible apparently by placing the condensing dome into the arc chamber whereas in the conventional type rectifier, it is mounted on top of the arc chamber. The diameter and height of the arc chamber are the same as for our conventional 750-kw. 600-volt rectifier. But in my opinion this advantage of compactness has been purchased at too high a price for it has necessitated the placing of additional water cooling cylinders at points within the chamber where they are much exposed to the heat of the arc—an innovation that is perhaps dangerous.

The claims of this new sectional type rectifier are based on comparison of the conventional 500 and 3,000-kw. rectifier with a 3,000-kw. sectional type unit all at 600 volts direct current. No comparison is made between this rectifier and the conventional type in case of say 1,500 and 2,000-kw. 600-volt units or large rectifier units operated at 1,500 or 3,000 volts direct current. In other words, the author picked out the most favorable condition for his comparison and omitted all reference to medium size 600-volt units and units at higher voltages.

The arc drop curve for the sectional rectifier shown in Fig. 5, is substantially the same as for the conventional 750-kw. 600-volt rectifier built by other manufacturers. It is stated by the author that with increased tank capacity, the quality and reliability decreases and further that the outage time per year with 3,000-kw. rectifiers is several times as great as with 500-kw. units. My experiences do not check with this; in fact, I find the reverse to be true. This is independently confirmed by the 1931 Report of the A.E.R.A. which shows a 2 per cent higher availability factor for the 2,500 and 3,000-kw. units of which a total of ten units is listed as against twelve 500-kw. units. The sectional type 3,000-kw. unit has more electrodes, more seals, more weldings and several times as many auxiliaries and temperature control devices than the conventional type rectifier. One would expect, therefore, that its reliability would be inferior to the single tank arrangement.

As far as space requirements are concerned, there is a slight gain in floor space for a 3,000-kw. 600-volt sectional unit. Since, however, space for transformer equipment, switchgear, and control remains the same as for a single tank unit and the rectifier seldom occupies more than 35 per cent of the total substation floor area, the total gain in space is not of much account. The headroom requirements of the above mentioned unit are somewhat less than for a single tank type. Here again the space advantage is less pronounced in the case of 1,500 and 2,000-kw. 600-volt units and does not exist for 1,500 and 3,000-volt rectifiers which the author omitted to mention.

Contrary to statements made by the author, it has been found that the cost per unit of output decreases with larger capacity rectifiers. I find that for a 3,000-kw. 600-volt single tank unit, it is from 30 to 40 per cent lower than for a 500-kw. unit. Furthermore, in case of small units the auxiliary apparatus represents a large percentage of the total unit cost. This, however, is not the case with large rectifiers as they require about the same amount of auxiliaries as small tanks.

**Application of Mercury Arc Power Rectifiers*, by C. A. Butcher, A.I.E.E. JOURNAL, May 1927, p. 446.

The demand for rectifiers so far is not in sufficient volume that much could be gained from mass production. Also in any event it would seem that even this small volume will require more than one tank size to take care of all requirements; *i. e.*, low-voltage and high-voltage units. Mass production, therefore, is hardly feasible; nevertheless, individual parts, such as, anodes, etc., can and are produced in quantities even with conventional type rectifiers.

It appears to me that the claims made for this rectifier have been somewhat over emphasized. Experience has shown that small sectional types have usually been later supplanted by large single tank types for reason of simplicity and reliability except in very special cases where other considerations were dominant. This is particularly true on fluctuating loads, such as heavy traction service where a real gain in reliability is of more importance than a slight gain in efficiency.

R. E. Hellmund: Some of the discussion refers to the comparative reliability and availability of sectionalized designs versus large unit designs. A somewhat similar example taken from the transportation field is given as follows.

In the early days of a-c. main-line electrification, a great deal of discussion took place on the relative merits of locomotives having one or two large motors and those having many small motors, such as the New York & New Haven locomotives having the multiple twin-motor arrangement. Practical experience showed very quickly that the reliability and availability with the large motors were very low because such unavoidable accidents as the breaking of a single carbon might damage the large commutator and keep the locomotive out of service a great part of the time. In contrast to this, a similar occurrence in the locomotives having many small motors, that is, "sectionalized power," permitted the quick replacement of the damaged motor and resulted in much greater availability of the locomotives. This was not a matter of theory but rather one of absolute fact and experience, and naturally it has practically eliminated any desire on the part of designers or operators for locomotives having large single motors.

The same tendency would not be quite so marked in apparatus having but very few parts to get out of order, such, for example, as synchronous machinery, and in such cases the tendency is toward a few large units rather than toward sectionalization. The mercury arc rectifier, however, in its present stage of development is not in this latter class. It involves the fulfilment of various severe and difficult requirements, such as tightness of a great many welded and other joints, as well as absolute cleanliness both during the construction of the rectifier and during repairs in the field. The smallest defect in either direction results in troubles and in failure. I have no doubt that under such conditions as these the sectionalized design will in the near future demonstrate its superiority over the large unit design from the standpoint of both maintenance and availability.

A. L. Atherton: Mr. Hull indicates disagreement with the reasons on which the sectional arrangement of large capacity rectifiers has been based. In view of his standing as a scientist, we may accept his fundamental statements, especially since they deal with a point which is relatively well established and generally known. It seems, however, doubtful to me if we may so readily accept the application of these fundamentals. That part of the arc path within the shield around the anode is not increased in cross section with increase in size of the rectifier. If a single set of six anodes was used for the same total output in the large and small capacity rectifiers, we might assume this relation to be as he has stated but this is not the case in today's practise. The 3,000-kw., 600-volt rectifiers are made usually with either 12 or 18 anodes which gives a rating of 1,000 to 1,500 kw. per set as against 500 or 750 for the sectional arrangement and for the smaller conventional units. Similarly, throughout the arc the effective cross section is not increased with length as the tank size is increased. The barriers, constructional or otherwise, to retaining the same design parameters in the larger units as were used in the more fully developed smaller units, are likely to prove sufficiently permanent to prevent this kind of working out of large single-tank units.

As Mr. Hull has indicated, reliability is probably affected by the same factors as efficiency, since it depends on conditions in the gas path. I do not think that we have anything so simple to deal with as the obvious but rather negative thought that the arc does not tend to concentrate on a single point. The amount and condition of vapor available for conductivity, its state of rest or motion as a body, the interaction between arcs which are carrying current and paths which are expected to withstand back voltage, and many other complicating and complicated factors enter the question of reliability.

As is usually the case in a development or investigation in which all of us know a relatively small share of what is to be known, we shall each of us have to be guided by our available knowledge and beliefs at the time. The course of events will determine which is the correct procedure. This much seems to me to be quite definite; in its present state of development, the sectional rectifier does have a material and valuable advantage in efficiency over the single-tank units of large capacity. I think that the same relation holds for reliability factors. I think that the convenience of concentrating the manufacturing problem in a reduced number of sizes will offset the fundamental disadvantage of the requirement for a greater number of pieces and a greater amount of material. I may be wrong in believing that these advantages will be retained as the developments progress. Time alone can tell.

Mr. Gutzwiller's reference to the experience in making up larger capacities of parallel installation of smaller capacity units, adds to our overall picture and it demonstrates anew the fact that valuable procedures are not always recognized at first.

He refers repeatedly to the gain in efficiency as slight. This gain at 3,000 kw., 600 volts amounts to approximately 1 per cent. For average load conditions in metropolitan traction service and with usual power rates, this gain in efficiency is worth from $750 to $1,500 per year, or capitalized at 15 per cent, from $5,000 to $10,000 in first cost. This is from 10 to 25 per cent of the normal cost of a rectifier of this capacity. The magnitude of the gain is evidently a question of point of view.

Here again, we shall have to depend on time to give the final answer. In the meantime, we who think of sectional designs as desirable can take considerable comfort in the example Mr. Hellmund has given of a well known and definitely established practise of sectionalizing for the sake of just these same gains that we feel are secured by sectionalizing the large capacity rectifiers.

Preparing Substations for Electric Operation
Philadelphia to Trenton Electrification, P.R.R.

BY L. B. CURTIS[1]

Member, A.I.E.E.

Introduction

INVOLVED in the extensive electrification program recently announced by the management of the Pennsylvania Railroad between New York and Washington are approximately forty substations. Eleven of these, including those covered by this paper, are already in operation. A definite program for testing these substations before placing them in operation had evolved, and it was thought advisable to combine these tests in a single set of instructions. This has been elaborated somewhat in this paper.

Since Edgely substation is typical of the majority of the forty substations, it is used to exemplify the testing. The other substations included in the Trenton electrification are Frankford Junction, Cornwells, and Morrisville. The standard apparatus consists mainly of 4,500-kva. step-down transformers, high-speed trolley breakers, necessary 132-kv. and 11-kv. switches and breakers, and control equipment.

The testing may be separated into the following three groups:

A. Preliminary tests without d-c. control and a-c. power.
B. Tests with d-c. control but no a-c. power.
C. Tests with d-c. control and a-c. power.

Group A—Preliminary Tests without D-C. Control and A-C. Power

Current Transformer Polarity Test

Due to the fact that differential protection is employed in some instances it is imperative that the polarities of current transformers installed in the bushings of all power transformers and circuit breakers be correct. All protective relays receive their actuating current from these transformers. The end of the current transformer corresponding to the top of the bushing is lettered *a*, and is understood to have the same instantaneous polarity as the top of the bushing terminal.

Fig. 1—Edgely Substation Wiring Diagram

Fig. 1 shows the connections for checking polarity. A millivoltmeter is connected across the secondary of the current transformer about to be tested with the plus terminal attached to the *a* side. Two or three dry cells connected in series have their negative terminal connected to the bottom of the bushing terminal. When the positive terminal is touched to the top of the bushing, or on the "make" there should be a positive deflection on the millivoltmeter. A negative deflection takes place on the "break." When the current transformer is connected through to the control and relay board, the above test is repeated with the millivoltmeter connected across the test switch behind the board. Every current transformer is tested in a similar manner.

---

[1] Supervisor of Substations, P.R.R.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

Circuit Breaker and Transformer Oil Test

Samples of oil from all oil-filled equipment must be tested for electrical breakdown strength before the equipment is energized. At least six samples are taken in each case. With the electrodes in the test set spaced 0.1 inch apart the average breakdown value must not be less than 25,000 volts.

Transformer Megger Test

All transformers are meggered to test their insulation. Readings are taken from high winding to low winding, from high winding to ground, and from low winding to ground. All readings must be sufficiently high to insure the absence of moisture, short circuits, and grounds.

Power Transformer Tap Changing Device Test

The power transformers are equipped with a tap changing device on the top cover in order to vary the voltage ratio between the high-voltage and low-voltage windings. A definite ratio is decided upon and all step-down transformers on the system are set on this tap.

Manual Operation of All Switching Equipment

All manually and electrically operated switches must be carefully adjusted for alignment and smooth operation by hand. No electrical operation of motor operated switches should be attempted before perfect operation is performed manually.

Electrical Interlock Test

In order to secure safety for the operators, and protection for the equipment, some of the apparatus are interlocked. The physical features of the interlocking parts should be carefully inspected so that all moving parts move freely.

Physical Check of All Relays

All protective relays are given a predetermined setting after an examination as to their condition. The relays are operated by hand to determine the contact adjustment and if any friction exists between movable parts.

Group B—Tests with D-C. Control but No A-C. Power

D-C. Energizing of Relay and Control Board

The combined relay and control board is now energized with the 125-volt control battery, one section at a time. Two lamps connected between the negative and positive buses and ground indicate whether any grounds exist.

Electrical Control and Indication Test

In the switch house on the control board there is a double pole switch that throws the control either on "station control," that is, control from the switch house, or "tower control" which is control from the nearest railroad tower. Every electrically operated piece of equipment in the substation is operated by means of the drum control handles on the control board both in the substation and in the tower. A green light indicates "open" and a red light "closed." Every operation and indication must be perfect.

Electrical Interlock Test

The apparatus that is interlocked together, some to open a load circuit in a breaker instead of in a disconnecting switch, and some to prevent a ground switch from being closed on a live circuit is now operated from the control board. The interlocking features must work every time.

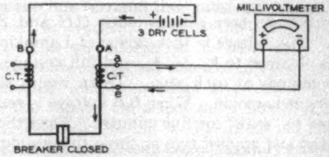

Fig. 2—Connections for Checking Current Transformer Polarity

Manual Relay Operation Test

The last test of this group is to check the relay operation of all equipment by causing the relays to function by hand. Inasmuch as the operation of these relays will be described under the a-c. tests it will be omitted here.

Group C—Tests with D-C. Control and A-C. Power

Preliminary

It is necessary to take the following precautions and preparations before these tests begin:

a. The entire catenary and transmission lines to be tested must be inspected for visible grounds and broken insulators.

b. A direct telephone connection must be had with the power director.

c. All temporary grounds at the substation must be removed except those on trolley feeders for tests one to eight inclusive.

d. Sufficient number of ground sticks for applying grounds must be on hand.

e. All necessary instruments for testing must be on hand.

f. A program of procedure must be set up and all involved in the test must have a copy so that it is thoroughly understood by all concerned what is to take place.

g. All interested in the test must be previously notified and be present when and where required.

Energizing Test of Transmission Line

The first of the a-c. tests is to build up the potential on the transmission lines. All 132-kv. line switches (132, 133, 232, and 233 in Fig. 1) are closed. The 132-kv. transformer horn-gap switches (1*H* and 2*H*) are opened. The voltage is then raised at Lamokin where power is obtained to ¼, ½, ¾, and full voltage, checking for grounds at each step. These would show on ammeters at Lamokin. When full voltage is reached it is allowed to "soak" for five minutes. Then the power is removed and applied two or three times suddenly at full voltage.

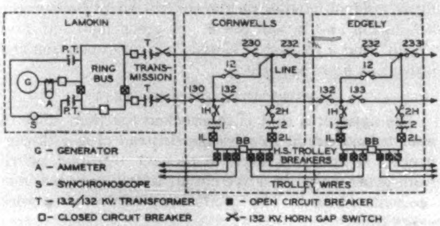

Fig. 3—Schematic Diagram for Phasing Tests

Energizing Test of Power Transformers

Both transformer horn-gap switches (1*H* and 2*H* in Fig. 1) are now closed, in addition to those in test 1. The voltage is built up as before, including the step-down transformers in the energizing.

Phase Test between 132-Kv. Lines and 11-Kv. Buses

a. The first step is to phase out the 132-kv. transmission lines. The 132-kv. line and tie switches (132, 133, 232, 233, and 12 in Fig. 3) are closed and all other switches and breakers opened. The voltage is built up and fed into one bus section at Lamokin from the generator, over one transmission line through the 132-kv. tie switch, and back to Lamokin over the other transmission line. If the pointer of the synchronoscope stops in the proper position the lines are in phase.

b. The next step is to phase through the 11-kv. bus instead of the 132-kv. tie switch. The tie switch 12 is opened and the transformer horn-gap switches 1*H* and 2*H*, the transformer low side breakers 1*L* and 2*L*, and the bus tie breaker *BB* are closed. The voltage is built up at Lamokin as in the preceding test.

Energizing Test of Entire Substation

All switches and breakers in the substation are now closed except the T-disconnect switches where the feeders leave the substation. The substation is energized with full voltage to allow the equipment and buses to "soak" for several hours in order to show up any defective insulation.

Calibration of Potential Device

While the substation is energized the potential devices connected to the 132-kv. bushings of the step-down transformers are calibrated. These devices furnish potential to the transmission line ground protective relays and must be calibrated for the particular relay used. A phase meter is used to read the phase relation between the system or reference voltage and voltage of the potential device. The watt component of the phase meter's burden should closely approximate in value that of the relay burden. The relay is blocked so it cannot operate and is disconnected during the test. The test connections are shown in Fig. 4. A condenser *C* is used across the phase meter in order to make the burden of the latter approximately that of the relay. A high resistance voltmeter is used to read the voltage across the potential device. The reference voltage is obtained from a potential transformer which is connected to the 11 kv. bus and should be constant during the test. A 100-watt lamp is used to obtain approximately one ampere 100 per cent power factor load. The values of reactors, transformer ratio, and condensers in potential device are varied so as to get a combination that will give approximately half reference voltage across the potential device, and the lowest possible phase difference. When this condition has been obtained the phase meter is disconnected and the relay reconnected.

The potential device on the other side of the transformer is then checked as above, and the same results obtained. The blocking may then be removed from the relay.

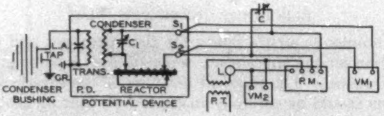

Fig. 4—Potential Device Test Connections

Reduced Voltage Ground Test on High-Speed Breakers

At Lamokin, jumpers are placed across the low- and high-voltage bushings of a step-up transformer so that generator voltage is impressed directly on the transmission line. The generator voltage is built up to approximately 11,000 volts which is reduced to 1,000 volts at the substation. With the 11-kv. bus dead, a high-speed breaker is grounded on the feeder side to the substation steel with a ground stick. This is indicated by × *U* in Fig. 5. Then all switches and breakers in the substation are closed except the disconnect switches on the out-going feeders, and the high-speed trolley breakers. The grounded breaker is then closed from the control board in the switch house.

The oil breakers are controlled from a set of three relays; impedance, load compensating, and instantaneous and time delay which are fed from current transformers located on the bus side of the trolley breaker. The load compensating relay can be considered as a part of the impedance relay, by changing the resistance value in series with the restraining coil of the latter. The impedance setting of the impedance relay is equal to 9/10 of the impedance of the trolley section to which the corresponding breaker is connected in order to avoid getting any overlapping of protection caused by inaccurate calculation. There is a directional element in series with the impedance element so that the relay will operate only when the fault is on the trolley or feeder side of the breaker.

The instantaneous and time delay relay has two overload elements, one high-speed with a current setting, and the other time-delay with a lower current setting. When a ground occurs close to one substation such as the one imposed above, the impedance relay will usually open the breaker feeding the fault. At the next substation, the breaker at the other end of the line will be opened by the high-speed element of the instantaneous and time delay relay. The impedance relay at this point being outside the setting zone will not operate. When the ground occurs midway between two substations the breakers feeding the faulty line will be opened by the impedance relay. The time delay element of the instantaneous and time delay relay acts as a back-up protection and also functions to clear stub end faults at minimum generating capacity.

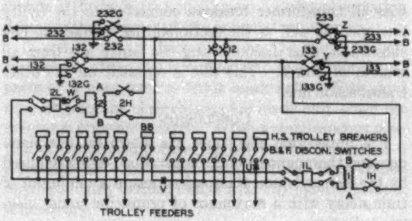

Fig. 5—Location of Grounds—Edgely Substation

The high speed air trolley breaker operates from either of two independent devices serving different purposes, a high speed device which is a part of the breaker, and a directional overcurrent, undervoltage relay.

The high speed device operates on a sudden current increase which is characteristic of a ground. It does not operate in the case of a gradually increasing current. The directional overcurrent, undervoltage relay takes care of this condition. This relay is fed from a current transformer on the trolley feeder side of the breaker. As the current demand increases, the voltage drops, and if this condition reaches a predetermined value the relay will operate to open the breaker.

If the oil or air breaker as the case may be operates satisfactorily, the bus is killed, and the ground stick applied to the next breaker. Every high speed trolley breaker is tested in this manner.

Reduced Voltage Ground Test on 11-Kv. Trolley Buses

A ground is now imposed on one of the 11-kv. trolley buses as shown in Fig. 5 at *V*. All breakers and switches in the substation are closed except the switches on the outgoing feeders, and the two transformer breakers 1*L* and 2*L*. A bus ground is caused by closing these two breakers simultaneously.

The bus differential protective relay is connected to current transformers located on the side away from the section to be protected of the bus tie breaker, the corresponding transformer breaker, and the trolley feeder breakers. The sum of the currents leaving the bus through the trolley breakers connected to one bus section under normal conditions is equal to the current entering the bus through the transformer breaker plus or minus the current flowing through the bus-tie breaker. The secondaries of all the above current transformers are connected together in such a way that under normal conditions there is no current flowing through the relay. On a bus short circuit or ground, however, this equilibrium is disturbed and the relay operates. This energizes a set of auxiliary relays which opens all breakers connected to the faulty bus section, and also a lock-out relay which locks open all closing circuits of these breakers so that they cannot be closed from the control board until the lock-out relay is reset by hand. The other bus section is tested as above.

Reduced Voltage Test for Transformer Internal Faults

A ratio differential relay is used to protect the 4,500-kva. step-down transformers against internal faults. A ground stick is attached near the trolley side of the low voltage bushing as shown at *W* in Fig. 5. If the test is made on No. 2 transformer the transmission line horn-gap switches 232 and 233 (Fig. 5) of the transmission line feeding this transformer should be opened. The other transmission line is energized with the reduced voltage, and 1*H*, 2*H*, 1*L* and *BB* are closed. The ground is caused by closing breaker 2*L*.

The ratio differential relay is energized by two sets of current transformers, one set consisting of two cross-connected current transformers on the high voltage side of the step-down transformer, and the other of a similar combination on the bus side of the transformer breaker. The relay has an operating coil and a restraining coil, there being no current flowing in the former under normal conditions. When a fault occurs in the transformer the balance between the two sets of current transformers is disturbed and the unbalanced current flows through the operating coil causing the relay to operate. This causes the transformer breaker 2*L* to open and after a sequence of operations which allows the fault current to decrease to safe value, the transformer horn-gap switch 2*H* opens thus isolating the faulty transformer. The test is then repeated on No. 1 transformer.

PHASING AND INSULATION TEST OF CATENARY SYSTEM

The reduced voltage tests having been completed the catenary system is now tested for insulation and phasing using the same system set-up as for test 3, except that the ring-bus at Lamokin is not sectionalized. The temporary grounds on the out-going trolley feeders are removed and all breakers and switches are closed. The voltage is raised to ¼, ½, ¾, and full voltage, thus energizing the entire catenary system as far as the test is to go. If the generator ammeter at Lamokin registers zero the trolley system is properly phased and the insulation is good. If there is a current flowing the trolley feeder breakers should be opened one at a time until the faulty section is located.

FULL VOLTAGE GROUND TEST ON TRANSMISSION LINES

After full voltage ground tests are made on high-speed breakers similar to test 6, the transmission lines are tested at full voltage. Reduced voltage tests are also made but as the operation is the same for both tests one description will suffice.

The transmission line ground protection as stated in test 5 is obtained with a differential relay which receives its potential from condenser potential devices. The ground is obtained by closing one leg of the 132-kv. ground switch, the other leg being previously disconnected from the motor-operated mechanism when the system is dead. The location of this ground is shown at *Y* in Fig. 5.

When a ground occurs on one side of the transmission line the voltage on that side of the potential device approaches zero depending upon the nature of the ground, and the voltage on the other side approaches 110 volts. The balance in the relay being disturbed, it operates, causing the corresponding step-down transformer breaker to open. This same operation takes place at each substation feeding into the faulty line. In Philadelphia at D-1 substation, the line is sectionalized by a 132-kv. breaker which also opens, thus disconnecting the faulty transmission line from all sources of power. The same test is performed on the other transmission line.

FULL-VOLTAGE SHORT-CIRCUIT TEST ON TRANSMISSION LINES

The 132-kv. transmission lines are protected from short circuits by means of directional control relays. The short circuit is caused by closing both sides of the 132-kv. ground switch. The trolley feeder network supplies power to the short circuit through all step-down transformers connected to the faulty line. The power flow is thus in the reverse direction from normal and is used as an indication of fault conditions.

The directional control relay has an overcurrent element which receives its current from a current transformer located on the low-voltage side of the 4,500-kva. step-down transformer, and a power directional element receiving potential from a 11,000/110-volt potential transformer connected to the corresponding trolley bus section. The directional element contacts must be closed before the overcurrent element can start to operate. The operation of this relay causes the corresponding transformer circuit breaker to open. Likewise all transformer breakers connected to the faulty line open as well as the sectionalizing breaker at D-1 substation, thus disconnecting the faulty line from all sources of power. This test is repeated on the other transmission line.

CONCLUSION

It is hoped that this paper has shown the completeness and thoroughness of the substation testing required by the Pennsylvania Railroad to insure a minimum of train delay with a maximum of protection under electric operation.

ACKNOWLEDGMENTS

Acknowledgment is hereby made to Mr. J. Westby for his care and interest in reading over this paper in its preliminary form and in offering valuable contributions.

Instructions prepared by Gibbs & Hill, Consulting Engineers, for use in the operation of the above electrification were of assistance in preparing this paper, particularly in describing the relay operation.

Acknowledgment is also made to two manufacturers who furnished most of the equipment in the above substations for reading over this paper and in offering many helpful comments.

Time and Its Measurement

BY ERNEST W. BROWN*

Non-member

THE nature of time and its relation to space in the theory of relativity, is not discussed here but it is assumed that, for our purposes, the Newtonian definitions give a sufficiently accurate picture.

DEFINITION OF A TIME-KEEPER

A time-keeper, whether terrestrial or celestial, may be considered as consisting essentially of a fixed dial and a moving pointer. A complete observation can be regarded as a comparison of the angles described by the pointers of two time-keepers between two signals, at each of which the positions of the pointers are simultaneously observed. This comparison of angles is then translated into a comparison of intervals of time by means of certain assumptions made as to the nature of time. In our daily life one of the time-keepers is used as a standard for judgment of the other which may, for example, be the interval between the departure and arrival of a train or that between the successive demands of the body for nourishment. Every observation demands the presence of two or more time-keepers.

In order that an observation may be made, the circumference of the dial is divided into two or more equal parts or it may have a single mark only. With some time-keepers the observations are made only when the pointer is opposite a mark. When a simultaneous position of the second pointer cannot be well estimated, a simultaneous observation with a third time-keeper, having a highly divided dial or a rapidly moving pointer, is necessary.

The pointer is actuated by a mechanism which is governed by the laws of motion. In some mechanisms the law of gravitation also plays a leading part: in others, physical laws of a different nature are mainly responsible for its motion. Most of the terrestrial mechanisms are constructed by human agency and are therefore under a certain degree of control. Celestial mechanisms can not be controlled.

ERRORS

Since our ability to deduce results from these mechanisms is limited and is subject to error, the discussion resolves itself from the outset into a consideration of the errors which may exist when an observation is made.

It will be convenient to divide these errors into three classes:

1. Lack of precision in the statements of the laws under which the mechanism is supposed to move.

2. Errors in the applications of these laws to the mechanism.

3. Errors in the reading of the pointer, usually called errors of observation.

From the practical point of view, Newton's three laws of motion on which our chief time-keeper, the earth, rotating on its axis, is mainly dependent, may be regarded as possessing an accuracy far beyond our powers of detection. The same may be said of the Newtonian law of gravitation in the practical applications to time measurement. Less accurately known are the laws governing the kinetic reactions of matter usually stated under the terms, elasticity, rigidity, hysteresis, etc. Perhaps in the same class can be placed the phenomena classified under the terms electricity and light. With the earlier time-keepers these have been used only for the transmission of signals where the accuracy for time-keeping purposes is very high; in the latest time-keeper, the oscillating crystal, electricity has become part of the mechanism

Errors in the application of the laws are usually numerical or mathematical; these can be eliminated. A more frequent source of error is the omission of the effect of known or unknown reactions of matter, such as friction, elasticity, etc. Errors of observation of terrestrial time-keepers are largely under control and can be eliminated to almost any extent by the development of suitable devices. Those of celestial observations are numerous: some follow known laws and can be allowed for to a greater or less extent; others are unknown and their effects can be discovered by indirect methods only; still others which appear to have no systematic character are supposed to follow certain laws of error and are reduced by multiplying the number of observations.

STANDARD TIME-KEEPERS. DEFINITIONS OF ERROR AND CORRECTION

The use of the word error implies the existence of a perfect time-keeper. No such mechanism exists. We can only make comparisons between different time-keepers. Any definition to be useful in practise must take this fact into account.

The error of a time-keeper at any instant is the difference between the reading of its pointer and that of another time-keeper which has a similar dial and whose pointer is constructed to have the same angular velocity, the latter being used as a standard. The angular velocity of the pointer of the standard may be different from that of the first time-keeper provided its dial is proportionately divided. The "accumulated error" in any interval is the difference of its readings at the beginning and the end of the interval, less the corresponding difference of the standard. The error is taken to be positive when the pointer is in advance of that of the standard. Thus, the error of a time-keeper includes

---

*Yale University, New Haven, Conn.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

that of the standard. They may be partially separated only by the use of the theory of errors applied to numerous time-keepers observed on many occasions. With an actual mechanism as a standard, the position of its pointer must be corrected for any errors which are known.

Fundamentally, all our observations can be considered as those of angles, but it is convenient to express them in time. The angular error of a time-keeper is expressed in time by its ratio to the angle described by the pointer of the standard in a given interval, multiplied by this time interval. Since the errors with which we deal are usually small, whether of the time-keeper or of the standard, the error of the standard has little effect in this translation of an error of a time-keeper from angle to time and can ordinarily be neglected. In future it will be supposed that this translation has been made.

The *correction* of a time-keeper is the amount which must be applied to it in order that it may agree with the standard. It has, therefore, the opposite sign to the *error*.

DEFINITION OF RATE AND CHANGE OF RATE

The *rate* of a time-keeper is less easy to define accurately. The average rate over a given interval is perhaps best defined as the ratio of the difference of the readings at the beginning and end of the interval to the corresponding difference of the standard in the same interval. The real rate at a given instant is the limit of this ratio as the interval approaches zero, but as this is not measurable, average rates must be used. Unfortunately, the word "rate" is used sometimes in this sense and sometimes as meaning the difference of this ratio from unity, expressed in terms of the standard. Thus if we talk of a time-keeper having a daily rate of $+1^s$ we mean that at the end of a day the reading is behind that of the standard by an angle which is 1/86400 that described in a day by the standard. The rate of a time-keeper thus defined is positive when it is losing on the standard.

A daily change of rate is the difference of the rates thus measured on successive days.

TIME-KEEPERS WHICH DIVIDE INTERVALS OF TIME

In the description of the dial and pointer illustration it was mentioned that with some time-keepers the position of the pointer could be observed only when it was opposite a mark. Different kinds of time-keepers are needed, some of which can be observed accurately at more frequent intervals than others. The dial may be divided into more parts or the pointer may revolve more rapidly. We thus have a second function of the time-keeper, that of dividing an interval into equal parts.

Our fundamental standard is, in theory, observed once a day and the chief function of the terrestrial clocks has been to divide this into 86,400 equal parts called seconds, the equality of the parts being a fundamental aim of the mechanism. For smaller divisions, various devices known as chronographs, are employed, the accuracy with which these can be constructed to divide the second into any number of equal parts being far in excess of practical needs.

THE FUNDAMENTAL STANDARD

As stated, the fundamental standard for time measurement is the rotation of the earth about its axis. According to the laws of motion, certain ideal bodies will rotate about their axis with constant angular velocities. Most of the apparent deviations of the actual earth from such an ideal are calculable or measurable or both, and can be applied to the observations. One, which will be mentioned later, has been made definite only within the last few years and is of considerable importance.

With this standard, the pointer is the telescope of the transit instrument and, in theory, the dial is marked with a single star only, so that the observations are made once only in each revolution, that is, when the pointer is on the star. In practise, however, many stars are used, the time from one to the next being carried by the astronomical clock whose rate is afterward determined by the observations.

ERRORS OF THE FUNDAMENTAL STANDARD

The errors of the dial of this time-keeper are those of the angular positions of the stars relatively to one another and of their relative motions; these have been reduced to very small quantities by numerous observations and thus the relative position of and motions of these "clock stars" are known with high accuracy. Next comes the personal error of the observer in recording the time on the clock when the pointer is on the star. This error again, partly by mechanical devices, partly by experience, and partly by measurement, can be nearly eliminated. Next the errors due to movements of the instrument and of its parts relative to the ground on which it is placed, are under a certain degree of control and measurement. Finally, there are anomalous refraction errors due to the movements of the atmosphere and others due to the local movements of the ground relative to the whole earth which are probably very small but which are not under control.

Under the best conditions none of these circumstances should produce serious accumulated errors over periods of a few days or longer. Meridian observatories of the first class expect to be able to give the daily time within one or two-hundredths of a second. But considerable doubts concerning the actual accuracy must be entertained as long as these observatories show differences amongst themselves running up to one or two-tenths of a second and persisting for weeks or months at a time. There is too little known about the nature or causes of these differences for any one observatory to be able justly to claim substantial superiority over all the others in the accuracy of its time determination. The day-to-day accuracy permits of tests; the week-to-week or month-to-month accuracy is doubtful.

CHANGES IN THE RATE OF THE FUNDAMENTAL STANDARD

The important exception in our knowledge of the deviations of the rate of rotation of the earth from constancy has been demonstrated by observations of the moon, sun, planets and satellites. In the comparison of gravitational theory with observation of these bodies, they agree substantially with one another in their measure of the time and disagree with the earth. The nature of these variations is such that errors in theory or observation as their source are highly improbable. Quantitative calculations also indicate that they arise from forces which act below the earth's crust. Calculation and dynamical theory then indicate that one result of their action must be changes in the external radius of the crust.

These changes of rate of our principal time-keeper are irregular. Ordinarily they are very small and can be detected as having occurred only in the discussion of observations of the moon. But there have been two occasions when no doubt concerning their orders of magnitude can be raised. During the interval 1893 to 1900 the rate can not have diminished by less than one part in 30,000,000 and was probably greater. Again within two or three years of 1917 it increased again by about one part in 40,000,000. The chief doubt is the interval during which each change was completed; it may have been anything less than seven years in the first case and less than five in the second.

The complete technique by means of which these changes are demonstrated is so highly specialized and so laborious to carry out that few living investigators have been able to examine it in detail. The results depend for their reliability on several investigations which have been published within the last eighty years and which have been carried out by different methods. The observational effects are so large, speaking relatively, that no doubt can be entertained regarding them. The rejection of them implies that an astronomically determined unit rate may sometimes differ from its average value by as much as one part in 30,000,000: their acceptance permits the error to be later reduced to about one-tenth of this amount.

COMPARISONS BETWEEN TIME-KEEPERS

It will be seen that there are considerable differences in practise between the accuracy which is attainable in the comparison of two or more time-keepers in the past, at the present moment and in the future. High accuracy in many astronomical determinations depends on the multiplication of the observations. Slow systematic changes of rate can only be determined by observations spread over a considerable length of time. Other changes of rate cannot at present be predicted. No method of judging the accuracy of a time-keeper is of general application unless it specifies the nature of the errors under consideration, the length of the interval over which it is to be judged, and the standard with which it is to be compared. While mention of an ideal time-keeper may give mental satisfaction, it has no place in actual measurements. Indeed, the tendency of modern physics appears to lean towards the abolition of all consideration of hypotheses which assume the existence of phenomena which cannot be observed.

MEAN SOLAR TIME

The direct use of the fundamental standard is confined to the astronomical observatory: it is more convenient for the layman to use an intermediate standard which is related to the position of the sun. For purposes of definition we can regard this time-keeper as a pointer referred to a mark on a dial which is made to move with constant angular velocity, this velocity relative to the fixed stellar dial having been previously determined by observation and gravitational theory.

In the early stages of human history, the mark on the moving dial was the actual sun. It was later found that such a mark judged by the stars was in advance or behind its average position by as much as one per cent in the course of a year. Later still gravitational theory enabled the astronomer to calculate the deviation very accurately and finally, by observations extending over a long interval of time, to obtain the average velocity also with high accuracy. The moving dial makes a complete circuit in the same time that the pointer takes to make some 365 circuits.

In practise, the astronomer compares the time shown by transit observations of the stars with his "sidereal clock" constructed to have the same rate. For the layman he translates this into civil time by calculation. The instant at which the day shall begin is a matter of agreement and definition.

The mean solar day is the interval between successive coincidences of the pointer with the moving dial. The mean solar second is 1/86400 of this.

GRAVITATIONAL EFFECTS ON PENDULUM TIME-KEEPERS

This paper concludes with a few remarks concerning the astronomical and geophysical forces acting on certain types of terrestrial time-keepers. All of the latter which are in practical use for accurate time-keeping are oscillators. These are of two types, those which oscillate principally under the action of the laws of gravitation and those whose oscillations are controlled chiefly by that property of matter which we call elasticity. As far as we know, the latter are practically independent of gravitational action or can be made so. They need not, therefore, be further considered in this connection.

The pendulum clock depends mainly on gravitational action for its motion and any change in this action may alter its time-keeping properties. As far as the gravitational actions of outside bodies are concerned, no practical effect can be detected. Just lately, for the first time, the action of the moon, which is the greatest external effect, was measured by the Loomis chronograph and shown to give accumulated errors which were always less than two ten-thousands of a second as indicated by theory. This also included those indirect effects caused by the moon such as tidal action both in the oceans and in the change of shape of the earth, etc.

A much more serious effect can be produced by a change in the distance of the pendulum from the center of the earth. If the clock be raised one foot, its rate will be changed by one part in twenty million and the accumulated loss as a time-keeper will be one and a half seconds in a year. The changes in the rate of rotation of the earth have been mentioned previously. Under two extreme hypotheses, the outer radius was changed near 1897 by 5 in. or 12 ft. The former change would have meant an accumulated error of the clock of $0^{s}6$ in a year; the latter 18^{s}. In either of these two cases the star transits would have shown 1^{s} as against the moon. Thus the comparison of the clock with star transits would have shown an apparent gain of $0^{s}4$ in the one case and an apparent loss of 17^{s} in the other. If any such change as the latter takes place in the future within an interval of a year, it can certainly be detected by the averaging of results of the Shortt clocks which are now in operation under the best conditions. Even if the change took three or four years to complete, it probably could still be detected. It must be remembered, however, that it is an extreme hypothesis constructed to account for a certain phenomenon, without any collateral evidence as yet to support it. The hypothesis may be good for a smaller value or it may have to be rejected altogether. At present, it appears to be necessary qualitatively, whatever the quantitative value may be.

Discussion

For discussion of this paper see page 550.

Modern Developments in Precision Clocks

BY ALFRED L. LOOMIS* and W. A. MARRISON†
Non-member Associate, A.I.E.E.

AT THE beginning of the present century it was believed by many that the limit of accuracy attainable by mechanical clocks had been reached. This presumption was based on the performance of specific mechanisms which had indeed been brought to a high state of perfection, but this presumption did not allow for the possibility of other *types* of mechanism for measuring time nor for certain refinements that have since then more than doubled the accuracy and reliability of the best clocks then available.

In 1911 Lord Grimthorpe wrote[1] "It seems to follow that the extent to which astronomical clocks can be made accurate, *viz.*, 1/30 of a second average variation from their mean daily rate . . . is a degree of accuracy sufficient for present purposes, and it seems rather doubtful whether mechanical science will, in the case of clocks, be likely to reach a much higher figure."

As the words clock, chronometer, etc., have come to have definite technical meanings in the art, we shall use the more general term "Timekeeper." In the broadest sense a timekeeper may be defined as any physical means that can be used for the subdivision of time into intervals known in terms of a standard time interval. Thus any periodic phenomenon can be adopted in a timekeeper, provided its period can be recorded in terms of another. In this sense the earth and the moon are timekeepers, as well as vibrating pendulums, tuning forks, and other sustained oscillators. As all man-made timekeepers are essentially "oscillators" we will consider first the equation of motion of a simple oscillator which can be expressed as

$$M\ddot{x} + R\dot{x} + Sx = A \sin (\omega t + \phi)$$

where M corresponds to the mass, R to the resistance or damping and S to restoring force proportional to displacement x. The right hand term represents the sustaining force required on account of the dissipation of energy in the oscillator.

For an oscillator to be a perfect timekeeper, all of the quantities, M, R, S, A and ϕ must remain invariable. While M and S are the chief rate governing quantities, the others are, from a design point of view, the most difficult to control.

The ultra precise practical timekeepers of today can all be contained within two classes, depending on whether S (the restoring force) is

(a) Gravity (as in pendulum clocks)
(b) Elasticity (as in quartz crystal oscillators)

The second class is a development of the last decade and was made possible by the development of the vacuum tube and associated electrical circuits. Intercomparisons between timekeepers of the two classes provide a most valuable means for the study of changes in gravity and related phenomena. These two classes are discussed separately.

GRAVITY TIMEKEEPERS (PENDULUM CLOCKS)

Unfortunately the motion of a pendulum is not quite simple harmonic motion since the restoring force varies as the sine of the angular displacement (instead of directly as the displacement) and therefore the period is not truly independent of the amplitude. This can be seen from the equation of motion of the pendulum which in its simplest form, neglecting damping and sustaining forces, is

$$Ml\theta + Mg \sin \theta = 0$$

the free period T for any given angular displacement can be expressed by the series:

$$T = 2\,\pi \sqrt{\frac{l}{g}}\,(1 + 0.0625\,\alpha^2 + 0.00358\,\alpha^4 + \,.\,.\,.)$$

Where α is the maximum deflection from mid swing expressed in radians. The corresponding change in rate expressed in seconds per day is shown in the curve Fig. 1.

Various attempts have been made to construct pendulums having a period independent of arc. Huygens[2] demonstrated that a pendulum constrained to move in the arc of a cycloid under the influence of gravity would have a rate independent of arc, but mechanisms to accomplish this result have always introduced larger irregularities than those which they attempted to cure. Suggestions have also been made that an elastic restoring force could be used to supplement gravity in such a way that the sum of the two would make the restoring force directly proportional to the displacement. Loseby first made this suggestion in 1851.[3] But such an additional control robs the gravity pendulum of one of its greatest advantages, as the rate is markedly affected by changes in the elastic restoring force.

Practical design has been confined to keeping the amplitude small and to providing a governing action so that any slight increase in amplitude causes an opposing tendency to decrease the amplitude, and *vice versa*.

The old anchor recoil escapement[4] accomplished this by increasing the friction on the pendulum with increase of amplitude. The inertia escapement[5] in the Shortt clock attains a similar result without the serious disadvantage of introducing friction. This inertia escapement is based on the principle that a weight rolling down an inclined plane applies a greater horizontal force

32-52

to a slowly moving plane than to a faster moving one. A suitable inclined plane attached to a pendulum receives an amount of energy roughly inversely proportional to the amplitude, or to the velocity at midswing. As the amplitude increases, the energy delivered into the system becomes less. But in spite of these controls the amplitude does vary in fact, which at the present time probably accounts for more irregularities than any other factor. Dr. Jackson has shown[6] that if the daily amplitude is regularly recorded and the clock rate corrected accordingly, a number of the irregularities in the Shortt clocks at Greenwich can be explained.

If a direct amplitude control could be applied to a clock such corrections ought not to be necessary. Such a method is now being tried on a Shortt clock in the Loomis Laboratory. When the amplitude of the pendulum exceeds a predetermined amount by even 0.0001 inch, a signal is sent, via a pointed electrode which hangs in the evacuated pendulum casing, to a vacuum tube which operates a relay so that the next 30-second driving impulse is omitted. The electrode is so adjusted that about every fifth impulse is omitted in this way. It is found in practise that the device operates without the bob ever coming in contact with the electrode, so that no energy is taken from the pendulum by physical contact. The difference in amplitude between the operating and non-operating conditions is only about 10^{-6} cm. which corresponds to about 0.3 second of arc. Thus the mean amplitude can be controlled to within approximately 0.1 second of arc. In order to insure that changes in level of the whole clock mechanism will not be the direct cause of changes in amplitude through this control mechanism, the mounting for the control electrode is suspended so as to be free to swing in the same plane as the pendulum, though of course having a different period and being highly damped in order to avoid sympathetic oscillations. With this control the constancy of rate appears to be improved, but at least a year's record is needed for conclusive proof, as the variations which this device seeks to control usually only occur at intervals of several months.

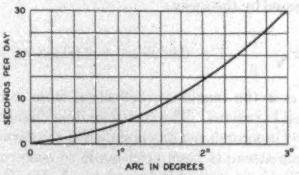

FIG. 1—CHANGE OF RATE OF PENDULUM WITH SEMI-ARC EXPRESSED IN SECONDS LOST PER DAY

The complete solution for the period of a pendulum swinging in a resisting medium, such as air, involves a factor $\sqrt{1 + kR^2}$ where R is the resistance to motion and k is a constant depending on the structure of the pendulum and the nature of the drive. Although it would appear from this that all pendulums should be operated in a high vacuum, practically it has been found[7] that the most satisfactory pressure for the Shortt clock, from the standpoint of stability of period with pressure variation, is about 15 to 20 mm. of mercury. When the pressure is very low or zero the arc, when not definitely controlled, is very unstable and causes large changes in rate, but in the neighborhood of 15 mm. of pressure there is a stabilizing action due to the air friction, and a neutralization of the following four effects of pressure variation:

1. Change in the restoring force due to buoyancy of pendulum in air.
2. Change of center of gravity due to buoyancy when pendulum is made of dissimilar materials.
3. Change of effective mass due to air carried along by the pendulum.
4. Change of friction and consequent change in arc.

The first and fourth are probably of greatest importance. With decrease in pressure the first decreases the period and the fourth increases it. At the critical pressure the two effects are about equal and opposite. In the determination of gravity,[8] where very precise pendulums are used, all of these factors must be considered very carefully.

When the amplitude control device described above is used, the pressure can be reduced to a small fraction of a millimeter, which thereby reduces the effect of friction to a minimum. The term $\sqrt{1 + kR^2}$ then becomes practically unity and the required sustaining energy can be very much reduced.

So far we have considered variations in the restoring force. Variations in the inertia term are now considered.

The expansion of the pendulum with temperature must either be reduced or compensated for. At the present time practically all clocks of high precision employ invar pendulum rods with bobs of type metal or invar. The bob rests on an expansion collar, the dimensions of which are calculated to compensate for the lengthening of the rod. Some recent studies[9] in Japan have produced a "super-invar," to use the expression given, which may have a zero or even a slightly negative coefficient of expansion. If these new alloys are as stable as invar, they may have an important use in precision clock making, as the entire pendulum could be made from a single piece of material.

With the new technique recently developed in the laboratories of the General Electric Company it is now possible to produce pieces of clear fused quartz large enough to construct the entire pendulum for a clock. Some experiments are now being conducted with such clocks in the Loomis Laboratory. Fused quartz has a temperature coefficient of expansion of about 0.5 parts in 10^6 per deg. cent. A temperature variation of one degree would therefore cause a change in rate of only 0.02 second a day due to this effect alone. In a constant temperature vault with a fused quartz pendulum a variation of 0.01 degree would only affect the rate 0.0002 second a day. Means have been developed whereby temperature can be controlled to within 0.01 degree over long periods.

There are two other major effects that should be considered in connection with pendulum length. These are (1) variations in the position of the point of oscillation, and (2) the instability of materials with time, in other words, aging. The effect of knife edge wear on the period of an ordinary pendulum is appreciable. A wearing of one thousandth of a millimeter will change the rate of a seconds pendulum nearly a tenth of a second a day. Largely for this reason, a flexible spring suspension of elinvar[10] is used in most precision clocks. But even the spring is suspected of changes in length and, what is just as bad, also of variation in stiffness which would change the point of flexure and the restoring force. Aging effects in the pendulum rod can be reduced only by finding better materials. It may be that fused quartz, or possibly some large single crystal, will be found finally to be the most suitable material to use.

The effect of knife edge wear on the period of a pendulum can in theory be almost entirely avoided by suspending the pendulum at a distance from its center of mass equal to the radius of gyration about that point. This simple principle of mechanics, has of course long been recognized,[11] and experiments are being conducted in Germany[12] and elsewhere to determine its value in a precision timekeeper. In the case of a uniform straight rod this distance should be $\frac{1}{2\sqrt{3}}$ of the total length from the center. With this condition fulfilled a change in this length due to knife edge wear of one part in a thousand would affect the period less than one part in a million.

Returning to the fundamental equation at the beginning of the paper

$$M\ddot{x} + R\dot{x} + Sx = A \sin (t + \phi)$$

we have considered briefly the terms on the left-hand side.

We will now consider the right-hand term—the driving force—and especially the quantity ϕ the phase angle, which presents perhaps the most difficult problem in the design of all timekeepers.

The impulse should be delivered to the pendulum at the time when the velocity is a maximum, that is, at the center of the swing, in order to reduce to the minimum the effect of variations in the driving force on the rate. If the impulse is applied *before* the instant of maximum velocity, the rate is momentarily increased. If the impulse is applied *after* the instant of maximum velocity the reverse is true. Of course the impulse actually is of finite duration and the desired effect is approximated by supplying the pulse symmetrically with respect to the instant of maximum velocity thereby tending to neutralize the above mentioned acceleration and retardation effects.

The necessity for this method of applying sustaining power pulses to a pendulum has been realized almost from the beginning of precision clock history but cannot be over-emphasized.

In the Shortt clock[13] the impulse to the master pendulum is controlled by means of an auxiliary or "slave" pendulum which in turn is automatically synchronized with the master pendulum to within ± 0.003 second at all times. The means by which this is accomplished can be seen from the schematic drawing Fig. 2 which shows the master and slave pendulums with all of the essential control elements, and the counting or time indicating dials. Although the master pendulum determines the rate of the system, the slave pendulum and associated mechanism does the work of releasing the driving pulses at the proper time. The slave pendulum, through a jeweled ratchet and pawl-operated count wheel, releases mechanically a weight arm once each 30 seconds at just the right time so that a small wheel on the gravity lever, rolling down a curved inclined track associated with the slave pendulum rod, imparts the sustaining impulse to it. As soon as the mechanical impulse is delivered, this arm closes an electrical contact which resets the weight arm, before the return swing of the pendulum, in readiness for the next 30 second impulse. The current which resets the slave clock drive also releases the impulse mechanism for the master clock thereby avoiding the use of *any* mechanical connection with the master pendulum other than that of the impulse wheel. As in the case of the slave drive mechanism, the impulse lever makes an electrical contact after delivering its impulse to the master pendulum, which resets the gravity arm and in addition operates the "hit and miss" synchronizer on the slave clock. The slave pendulum normally runs a little slower than the master and is speeded up when necessary by means of a spring attached to the pendu-

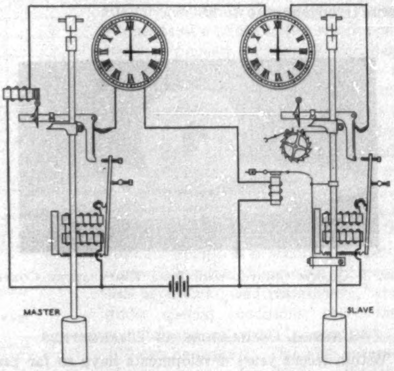

FIG. 2—SCHEMATIC DRAWING OF SHORTT CLOCK MECHANISM AND CIRCUIT

lum rod which is engaged by the synchronizer whenever the slave lags by more than 0.002 second behind a definite phase relation to the master.

There are reasons to believe, however, that small changes in phase do occur especially with variations in amplitude. Probably future improvements in gravity timekeepers will include improved methods for keeping the phase of the driving force more nearly constant.

It would be impossible even to survey adequately the developments leading up to the final design of any given type of clock in the limited space for this paper. It must not be assumed that the excellent performance of any timekeeping device is due entirely to any one person or company or period, but represents the combined efforts of a large number of people over an extensive period.[14,15,16] The three clocks most often recognized as precision timekeepers are the Leroy,[17] Riefler[18] and Shortt[13]. One or more of these is to be found in most of the important time laboratories and astronomical observatories throughout the world.

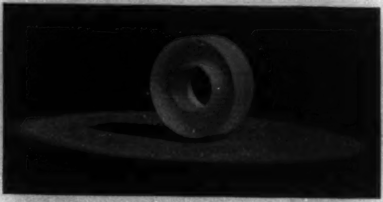

FIG. 3—QUARTZ CRYSTAL WITH ZERO TEMPERATURE COEFFICIENT USED IN CRYSTAL CLOCK

CRYSTAL OSCILLATORS AS TIMEKEEPERS

Within recent years developments have so far progressed that the constancy of rate of certain mechanical resonators, maintained in vibration by vacuum tubes, may be comparable with that of the best pendulum clocks. Such oscillators have the chief attributes of a good clock and can be used to operate or control a wide variety of time mechanisms with even greater versatility than the conventional pendulum.

The most accurate oscillators of this type known to the authors are controlled by plates of quartz crystal vibrating at a high frequency, that is, high in comparison with the frequency of a pendulum. Probably the most accurate of these at the present time are a set of four 100,000-cycle oscillators[19] that have been built by Bell Telephone Laboratories primarily for use as a primary frequency standard. These laboratories have also supplied a similar set of oscillators to the U. S. Bureau of Standards for the same purpose.

In this type of oscillator the frequency is controlled by a ring of quartz crystal about three inches in outside diameter as shown in Fig. 3. The frequency of the oscillator is the same as that of the crystal, that is, 100,000 cycles per second. One complete oscillator, including temperature and pressure controlled crystal, and shielded vacuum tube circuit, is shown in Fig. 4.

In order to operate clock mechanisms in the most direct way it is necessary to control from this high frequency another which is low enough to operate a synchronous motor. This is done by an electrical circuit known as a sub-multiple generator which controls one frequency at a definite fraction of another in absolute synchronism. Several types of circuit have been used for this, all of which are as positive in action as a set of gears. Usually the low frequency used to operate the motor is 1,000 cycles. Each pole on the motor in motion therefore corresponds to one milli-second in time and hence any variation in the motor mechanism or operation can amount at most to a fraction of a milli-second. Such a motor can be used to operate time indicating or measuring apparatus in a wide variety of forms.

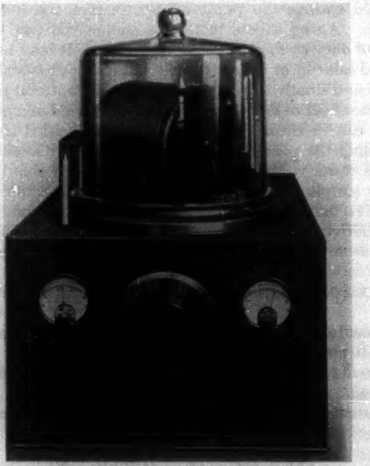

FIG. 4—COMPLETE 100,000 CYCLE QUARTZ OSCILLATOR

Including temperature and pressure controlled crystal and shielded vacuum tube circuit

As a rate controlling element a crystal of quartz used in this way has a number of outstanding useful properties. As previously discussed, the rate of vibration is controlled chiefly by the effective mass and stiffness of the resonator. On account of the chemical stability of the substance Si O_2 and the physical stability of the crystal structure of quartz these may be expected to be constant in very high degree. At the present time, variations introduced by the vacuum tube circuit and the crystal mounting are such that no conclusive evidence of aging in the quartz has been obtained.

Since the elasticity is a constant for such displacements as are required (amounting to less than one part in 100,000 change of dimensions) the rate is substantially independent of amplitude. The amplitude can be controlled at nearly a constant value, however, by proper adjustment of the vacuum tube circuit.

The temperature coefficient of frequency can be made as near to zero as required at any given operating temperature by properly adjusting the shape of the resonator. Crystals that have been in continuous operation for three years have not shown any appreciable change in this adjustment.

Crystals are not affected by gravity or magnetic fields and can be shielded readily from electrostatic fields. They can be mounted so as to be relatively immune to vibrations which always seem to be present in the earth, especially near traveled roads and manufacturing centers. This may be found to be an important factor in the location of accurate clocks in cities or near earthquake zones. The crystals referred to above are mounted on the seventh floor near a much traveled thoroughfare in New York City.

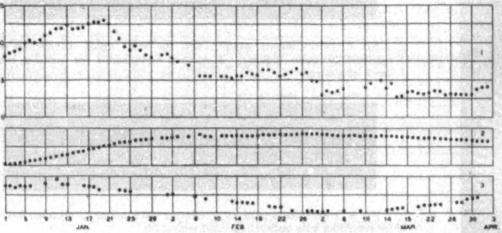

FIG. 5—PERFORMANCE DATA FOR CRYSTAL CLOCKS

Curve 1. Rate comparison between crystals 1 and 2 expressed as parts in ten million

Curve 2. Integral of curve 1, showing running comparison between crystals expressed in seconds

Curve 3. Indicated time of one crystal clock vs. corrected time signals from U. S. Naval Observatory

The electro mechanical coupling to a crystal for imparting the sustaining energy to it makes use of its piezo activity. As far as has been determined there is no increase in decrement directly due to this means of coupling, although, of course, properties of the electrical circuit, such as damping, may be manifested in the crystal through this coupling. The logarithmic decrement of a 100,000-cycle low coefficient crystal mounted in air at atmospheric pressure and coupled into the electrical driving circuit is about 0.00012.

Probably the largest rate disturbing factors in the crystal clock at the present time are due to effects of the phase ϕ of the applied driving force. This factor varies slightly with circuit variables, aging of vacuum tubes and power voltage variations. Developments now in progress indicate, however, that the effects of these variables can be greatly reduced, which should make a marked improvement in performance.

The performance, as clocks, of a pair of crystals is shown for a three-month period in the graph Fig. 5. The comparison rate curve shows the variations in relative rates between the crystals while the time comparison curve shows the variation in indicated time (integrated rates). The third curve gives the rating of one of the crystals against corrected Naval Observatory time signals for the same three-month period.

While the crystal clock assembly is more costly than a pendulum clock and requires more elaborate associated electrical equipment, we believe that for many purposes it is decidedly superior because of its great versatility. For example, its rate can be adjusted at will over a sufficient range to allow for such aging effects as occur. Also, the phase, or indicated time, can be adjusted with extreme accuracy. This can be done most advantageously in the electrical circuit by means of a phase shifter which operates continuously through 360 elec. deg., or any fraction or multiple thereof. If used in the 100,000-cycle circuit, one complete turn of the dial corresponds to a final adjustment of one hundred thousandth of a second, which obviously is greater accuracy than needed in any ordinary time mechanism.

The accuracy of inter-comparison of crystal clocks may be very high. An absolute comparison accurate to better than one-hundred thousandth of a second can be maintained continuously, while under special conditions, short time comparisons accurate to one part in 10^{10} can be made.[19] This high accuracy of comparison is due chiefly to the large number of vibrations per second, 200,000 times greater than with a "seconds" pendulum. Even greater accuracy of comparison could be obtained by the use of higher frequency crystals, but for reasons of convenience and greater freedom from the effect of external circuits and the mounting, the lower frequency is preferred.

One application of considerable interest is that two clock mechanisms can be operated from the same crystal control in this way so that one keeps true mean solar time when the other keeps true sidereal time.[20] It can be shown readily that any ratio of rates can be obtained for such a purpose accurate to at least one part in 10^{10} without the use of an unduly complicated mechanism. Lord Grimthorpe has shown why a pendulum cannot be used for this purpose,[21] but his reasons do not apply to the crystal control method.

By means of a shutter of the type shown in Fig. 6, and a photoelectric cell, signals of extreme accuracy can be controlled which could be used for radio transmission of time signals or for any purpose requiring great accuracy. When this disk is rotated at ten revolutions per second by a crystal controlled motor the current from the photo cell is 1,000 cycles modulated, in the manner indicated in oscillogram No. 1, at 100 cycles per second. By marking one 0.01 second element, as for example by partially blocking one sector, a positive 0.1 second indication is obtained. The oscillograms shown in Fig. 7 were made with the disk shown and indicate how, with the use of a suitable oscillograph, a continuous time signal can be recorded that can be read to a fraction of a milli-second. This resolution would be very useful for accurate time measurement work, for studies in radio propagation times, and for measurements of gravity. Observers requiring less resolution than this could obtain 0.01 second accuracy by the use of a rectifier and a recorder accurate to only 0.01 second. The same is true for 0.1 and 1.0 second accuracy by a suitable choice of transmitting disk and receiving equipment.

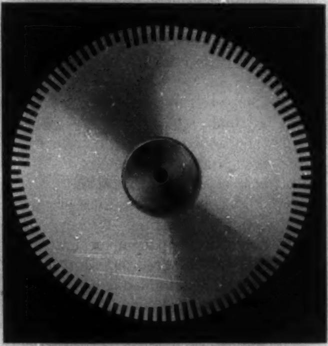

Fig. 6—Special Light Interrupter for the Production of Accurate Timing Signals by Photoelectric Cell

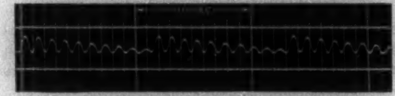
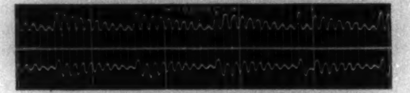
The second oscillogram shows the signal directly from the disk and after it had gone through a complete radio transmitter and receiver consisting of a total of eleven tandem vacuum tube stages and the associated equipment. As indicated, the total delay encountered was about 0.1 milli-second, and the distortion is not appreciable. Of course any combination of make and break signals can be controlled in this way using either a continuous or a modulated tone. If desired a series of half second dashes could be controlled, interspaced by a dot-dash code to designate each dash.

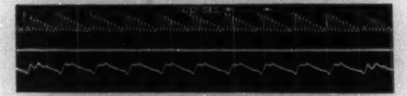
A complete time signal control mechanism based on this idea is shown diagrammatically in Fig. 8. In the method shown, light from a straight filament lamp is imaged on the slotted edge of a disk driven at 10 revolutions per second by a 1,000-cycle motor. The light entering the photo cell is modulated as indicated, at 1,000 times and 500 times per second alternately, and controls a corresponding electrical signal. The slow speed shutter, rotating at one revolution per second, causes the effective light path to alternate between the two disks once each second, and gives a corresponding variation of electrical signal. This signal can be used for any resolution from one second down to one milli-second and can be received through static and fading. It can be reduced to the dash-space type by the use of a simple voice-frequency filter to suppress the undesired half signal, or used as a continuous signal for oscillograph recording.



No. 1. Direct signal obtained from photo-cell



No. 2. Direct signal (above), and the same signal transmitted and received by radio (below). A method is indicated for marking every tenth of a second



No. 3. Direct signal as in No. 2 (above) and same signal rectified (below) for recording with only 0.01 second resolution

Fig. 7—Oscillogram of Time Signals Produced by Photo-Cell Method

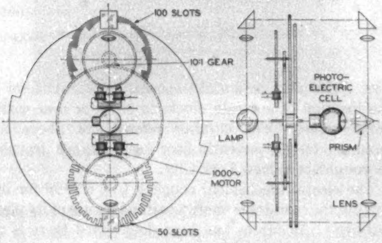


Fig. 8—Proposed Method for Production of Accurate Time Signals by Photoelectric Cell

Among the advantages of the crystal clock it should be mentioned that in order to control any number of clock mechanisms with the same precision it is only necessary to distribute the constant frequency current derived from the crystal to the separate mechanisms. This can be done on any scale economically feasible.

Performance of Clock Installations

In order to indicate the performance that may be expected of precision clocks, data have been obtained from several actual clock installations and presented herewith in the form of curves. These do not show in every case, perhaps, the performance that could be obtained under ideal conditions but they do indicate the type of performance to be expected under present normal working conditions. In studying these curves, care should be taken to examine the coordinates because it was impossible to present all the data plotted to the same scale on account of the different times and the different errors involved. Also some of the data are plotted as daily rates and others as indicated time. The effect of this is that over a short period a rate curve shows greater apparent variations than a time curve and *vice versa*. In some cases the mean gaining or losing rate was removed from the data, as this has no bearing on the *constancy* of rate which alone determines the value of a clock as a timekeeper.

The essential descriptive information concerning the clocks represented accompanies each figure. Some data relative to the performance of Shortt Clocks 20, 21 and 22 in the Loomis Laboratory and the Crystal Clocks in Bell Telephone Laboratories are discussed in the following section.

Experiments in Time at Loomis Laboratory

The clock installation at Tuxedo Park and some of the experimental results obtained there have been described elsewhere.[7] In brief it consists of three Shortt clocks mounted in an especially favorable location practically free from traffic and electrical disturbances, and carefully temperature controlled. The excellence of the location is enhanced by the fact that the clock vault is excavated in the solid rock of the mountain on which the laboratory stands, and the three massive masonry piers for mounting the clocks are effectively a part of this rock. One of the three Shortt master pendulums in its casing is shown in Fig. 14 mounted on its pier within the temperature controlled vault.

By means of the Loomis Chronograph[7]

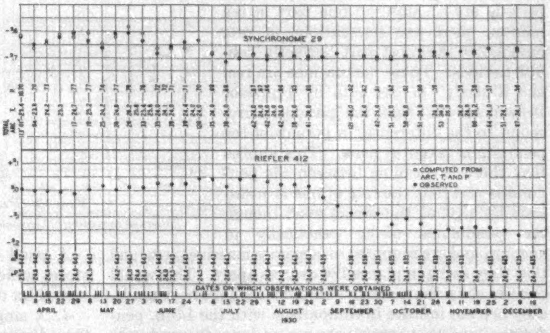

Fig. 10—Dominion Observatory, Ottawa, Canada

Observed daily rates of Riefler 412 and Shortt 29. (Data supplied by Dominion Observatory) it has been possible for the first time to obtain a running phase comparison of a number of clocks with great precision. Prof. E. W. Brown and Dr. Brouwer have shown[22] that the probable error of the mean hourly rates as measured by this chronograph is less than 0.0001 sec. With a resolution of this order, it is possible to study some effects that would be forever unsuspected with the use of any comparison equipment used heretofore.

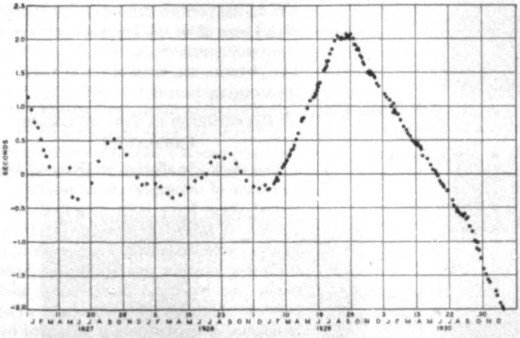

FIG. 11—ROYAL OBSERVATORY, GREENWICH, ENGLAND

Comparison of observed correction for Shortt clock No. 11 with those computed from the following formula which was based on observations from March 1927 to December 1928. Formula: $98^{s}905 + 28^{s}2002t + 1^{s}7542t^{2} + 0^{s}2524 \int (T\text{-}62^{o}8)\, dt$ + Nutation (Information from Monthly Notices of R.A.S. 1928-1931 inc.)

The rate curves on Fig. 15 will illustrate a case in point. These three curves show the differences in rates between the three Shortt clocks taken in cyclic order, plotted on a very open scale over a period of about three months. Although the *mean* rates over this and much longer periods are constant to one part in ten million, there are fluctuations in rate having for the most part perfectly definite periods. These fluctuations are real and a study[22] of the data by Professor Brown showed that the periods correspond to the differences in periods of the pendulums taken in pairs. This implies that there is coupling between the pendulums and that the rate of one is *modulated* by that of the others even though the pendulums swing practically in vacuum and are mounted on separate massive piers, and that they swing in planes 120 degrees apart. This would seem to show that, massive as the piers have been made, they are not infinite in comparison with the 14-lb. pendulums, and that strains are set up by each pendulum that are felt in some degree by the others through the piers and solid bed rock.

In order to indicate the comparison of these three Shortt clocks on the same basis as the Observatory clocks previously discussed, the data of the rate curves in Fig. 15 are replotted on the same graph on the basis of indicated time. This shows that although the rate variations are quite appreciable as measured by the Loomis Chronograph, the relative performance, as clocks, is all that could be desired, and indicates that factors having small but real effects on the rate can be detected by a chronograph with this high resolving power when they would not be observed at all by ordinary methods. The three rate curves and the three time curves are plotted to the same scale as the corresponding crystal data in Fig. 5.

The Loomis Chronograph consists of the following essential parts:

1. A strip of paper about 10 inches wide moving at a uniform rate between a long grounded electrode and a comb consisting of one hundred separate equally spaced pointed electrodes.

2. A distributor having one hundred segments separately connected to the one hundred elements of the comb, operated at exactly ten revolutions per second by a synchronous motor from a source of 1,000-cycle current.

3. A source of high potential consisting of an induction coil through the primary of which a large condenser is discharged when a record is to be made.

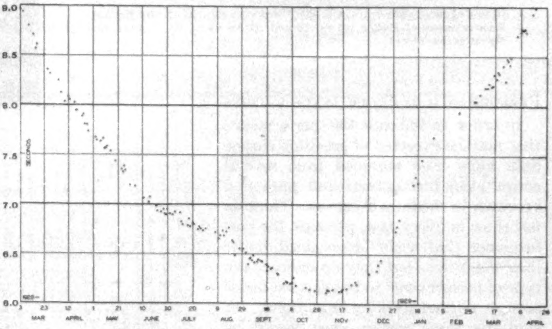

FIG. 12—PARIS OBSERVATORY, PARIS, FRANCE

Observed correction of Leroy clock No. 1185 (Information from Bulletin Horaire 1928-1930)

A small condenser on the induction coil secondary stores sufficient energy to produce an intense spark of very short duration; and

4. A single relay in the common circuit of all the time devices to be recorded on the moving paper strip.

Fig. 16 shows this chronograph in operation.

If the relay is operated every time the distributor makes some exact whole number of revolutions a series of perforations will be made in a line parallel with the edge of the paper. If in the time between sparks, the motor revolves a whole number of times plus or minus one hundredth, successive perforations will be displaced an amount corresponding to one milli-second in time. One second in time is represented by ten complete transits of the chart, so that, in effect, the chart is 100 inches wide and the effective recording element moves at the rate of 500 ft. a minute. Thus from the slope of the line of perforations with respect to the edge of the paper the difference between the rate of the distributor and the rate of the sparks can be determined with high precision. Similarly any number of separate sets of sparks can be recorded simultaneously on the same chart, using the same actuating relay and distributor. The relative rates may be determined by measuring the difference of slopes of the rows of perforations.

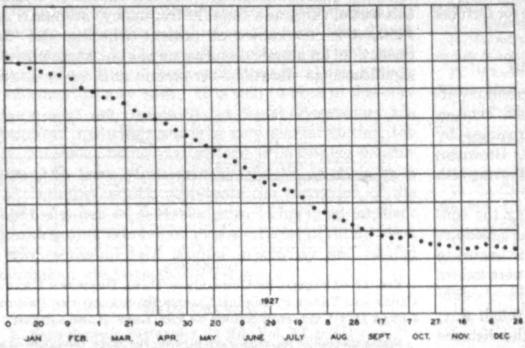

FIG. 13—ROYAL OBSERVATORY OF EDINBURGH, SCOTLAND

Observed correction of Shortt clock No. O. (Information from Proc. Royal Soc. Edinburgh Vol. XLVIII, page 161)

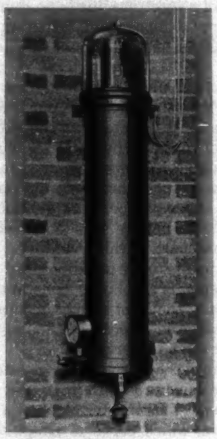

FIG. 14—MASTER PENDULUM (IN CASING) FOR ONE OF THREE SHORTT CLOCKS IN THE LOOMIS LABORATORY, TUXEDO PARK N. Y.

This is the method used for intercomparing the three Shortt clocks and for comparing them with the crystal oscillators in New York. To accomplish this, 1,000-cycle current controlled by the Bell Laboratories' crystal is sent over a private wire to Tuxedo and there used to drive the distributor as outlined above. The resulting records are continuous comparisons of the three Shortt clocks and the crystal accurate to better than one milli-second in time.

Since the crystal does not respond to variations in gravity while the pendulum does, the difference in rates contains a term having the period of the lunar day, corresponding to the direct gravitation effect of the moon on the pendulums. Several months' record of the Loomis Chronograph have been analyzed,[22] by Professor Brown and Dr. Brouwer and a lunar term observed having the proper period and magnitude. A graph of the lunar effect derived in this way is reproduced from

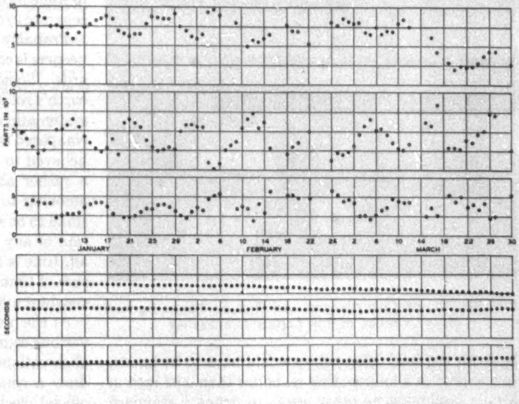

FIG. 15—INTERCOMPARISON OF THREE SHORTT CLOCKS IN LOOMIS LABORATORY

A. Rates, expressed in parts in ten million
B. Integrated rates expressed in seconds

their paper in Fig. 17. The periodic gain and loss in indicated time is about 0.0002 second per lunar day.

The results of time studies obtained at the Loomis Laboratory have been very encouraging and it is planned to continue the researches in clocks and time measurement methods. Some aspects of this work were discussed by Professor C. V. Boys in *Nature* for October 17, 1931.

POSSIBLE FUTURE INVESTIGATIONS

No doubt there is a practical limit to the accuracy attainable in a timekeeper but as long as random changes in rate are observed which cannot be explained by uncontrollable properties of matter (such as Brownian movement) that limit has not been reached, even with the types of mechanism at present in use.

The suggestion has been made of utilizing the constant velocity of light between fixed points as a measure of period. At present the velocity of light is known to less than one part in a million.[23] Even if it were known with greater accuracy, the practical difficulties of establishing such a standard, except in a very rough way, would be insuperable. In the first place the distance between the measuring points would have to be known to one part in a million, that is, better than 0.06 inch in a mile, assuming no other error, to define a standard good to only 0.1 second a day. Considering the difficulties in measurement, an accuracy of a little better than a part in a million is about all that could be expected of such a method by any means now known.

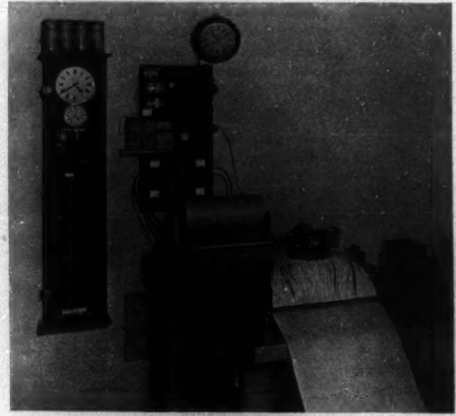

FIG. 16—LOOMIS CHRONOGRAPH AND ONE OF THREE SHORTT SLAVE CLOCKS IN THE LOOMIS LABORATORY

The extreme definition of some spectral lines indicates a very slightly damped oscillation of some sort in the atom, and some thought has been directed to means of making a frequency comparison between these vibrations and others of lower frequency that could be used to measure time as previously outlined. The effective logarithmic decrement of the "oscillator" behind the red line of cadmium can be estimated as about one tenth of that of a quartz resonator. The difficulties of utilizing this sort of thing as a time (or frequency) standard are: First, it is not known at present whether the "frequency" of an atomic disturbance has the same physical significance as vibrations-per-second and, second, even if the significance were the same, the orders of the two frequency ranges are so far separated that no means known at present could be used to effect the comparison. Besides, the energy of a spectrum line is no doubt made up of a large number of damped wave trains superposed in some fortuitous fashion as would cover the identity of separate cycles.

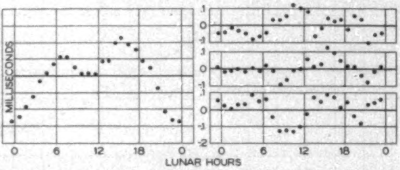

FIG. 17—ANALYSIS OF COMPARISON DATA BETWEEN CRYSTAL CLOCK AND THREE PENDULUM CLOCKS REVEALED THE PERIODIC LUNAR DAY VARIATION SHOWN IN THE LEFT HAND CURVE

Similar analyses of the comparison between the three pendulum clocks taken in pairs showed no corresponding effect

Probably the real final limit in the accuracy of timekeepers is concerned with the measure of our time standards. Some observations indicate that the rate of the earth's rotation is not constant, but that there are both systematic and apparently random changes in rate as compared with the motion of other astronomical bodies believed to be more stable.[24] For example; about 1918 a rather abrupt change in rate was observed which amounts to about one part in thirty million. This is small to be sure, but points to the improbability that the rate of any phenomenon is absolutely constant. After all, time is relative and the most nearly accurate measure of time must always be in terms of the most nearly constant motion that can be observed.

At the present time in the official observatories of the various countries the usual procedure is to plot the star observations in terms of their master clock and then to draw a smooth curve, which curve is adopted as the official clock correction. To some extent the drawing of this curve is a matter of judgment, based partly on the number and certainty of the star observations and partly on the estimated performance of the master clock in terms of their other clocks. These observatories at the present time also transmit and record radio time signals and publish periodically corrections to these signals in terms of their "standard clock error." From these data alone it is not possible for any one observatory to compare its clocks directly with the clocks in another observatory. If the observatories would publish one additional number for each of their important clocks, namely, the comparison of each clock with their official time, it would be possible to compare the rates of the clocks in such observatory directly with clocks anywhere else in the world where the radio time signals can be received. This would involve only a very small amount of additional work as the numerical data have to be obtained in any case. It is well to note in this connection that the United States Naval Observatory has adopted a procedure which is very similar to this, the only difference being that instead of publishing the corrections to each of its principal clocks, it publishes a single number which represents the correction of the weighted mean of several clocks. This is an excellent beginning and it is hoped in the interest of future clock developments and of studies in gravity and related phenomena, that others will follow.

Time Service of the U. S. Naval Observatory

BY J. FREDERICK HELLWEG[1]
Non-member

INTRODUCTION

THE U. S. Naval Observatory determines the standard time for the United States with scientific precision and broadcasts the results so as to make them available throughout a large part of the world. Since 1830 the Navy has had charge of this very important task. In the early days the demands for time service were confined principally to the mariners of our country. Scientific pursuits, increased demands of public utilities, greater business efficiency, increased speed in all activities of daily life, new inventions, all have demanded greater accuracy, and repeated expansion of the time service. At present the time service is broadcast six times a day and each broadcast is sent over a spread of about fourteen different frequencies to insure universal reception.

DESCRIPTION OF THE OBSERVATIONS WHICH ESTABLISH STANDARD TIME

The period of the earth's rotation on its axis is accepted as the standard of time measurement. The stars appear to rise in the east and after swinging across the heavens to set in the west. If a person stood on the earth's equator and measured the interval of time between two successive transits of a distant star he would have the most accurate measure of the rotation of the earth. If the same measurement was then made using the sun instead of a star the interval would be about four minutes longer due to the earth's orbital motion around the sun which continuously changes the apparent place of the sun among the stars. Therefore, as the earth rotates on its axis, this apparent motion of the sun necessitates the earth's rotating through more than 360 degrees to bring the sun again in the observer's meridian.

The stars are not within the earth's orbit, they are so far distant that their apparent positions are only very slightly affected by the earth's orbital motion. The positions of the stars are measured from a point in the sky known as the vernal equinox, and the period of the earth's rotation measured with respect to the vernal equinox is called a sidereal day. The same period measured with respect to the sun is called an apparent solar day. Owing to the variable length of the apparent solar day, astronomers had to devise a uniform measure of time and called it a mean solar day, so now we have apparent time, mean time, and sidereal time, and each time can be converted into the other by the application of the proper corrections. Because of the greater accuracy of sidereal time, that time has been universally used by astronomers.

In order to simplify the important question of time throughout the world, standard time zones have been established. All points within each zone use the same standard mean time although this may differ from their local time by as much as one-half hour. These zones represent a belt just one hour wide or fifteen degrees of longitude wide. In continental United States there are four zones:

Eastern Standard Time or 75th meridian time which is exactly five hours behind Greenwich standard mean time.

Central Standard Time or 90th meridian time, six hours behind Greenwich time.

Mountain Standard Time or 105th meridian time, seven hours behind Greenwich time.

Pacific Standard Time, or 120th meridian time, eight hours behind Greenwich time.

The Naval Observatory is thus able to furnish one time signal which provides time for all zones, not only in continental United States but for its island possessions and ships far out across the Pacific.

THE DETERMINATION OF THE STANDARD TIME

The Naval Observatory uses small quickly handled telescopes known as transit instruments in observing celestial bodies for the determination of our standard time.

These transit instruments as their name indicates are rigidly mounted so that there can be no motion either side of the meridian. The instruments are pivoted however so as to rotate from north to south. Astronomical bodies are therefore only visible through the transit instrument when on or very near the celestial meridian.

The sidereal time at which each star will cross the meridian is very accurately calculated. Stars are selected which cross the celestial meridian near the zenith of the Observatory and also whose positions are the most accurately known.

The observer operates a micrometer attachment which causes interruptions in an electric circuit as the star passes certain points in the field of the instrument. These interruptions are recorded graphically by a chronograph on the same sheet which records the standard sidereal clock ticks. By measurements of this sheet and the application of known corrections, the exact time of meridian transit is determined, according to that particular clock. The difference between this time and the previously calculated time represents the error of that clock on sidereal time. A continuous record of the standard clock corrections is maintained, determined

32-38

every clear night by observing a list of stars with one or more telescopes at the Observatory.

THE PROCEDURE USED IN BROADCASTING STANDARD TIME

Sidereal time is more convenient and more accurate for the use of the Observatory in rating the standard clocks, but it is not at all suitable for the general public.

The transmission of the time service is therefore in mean solar time and the transmitting clocks are rated to mean solar time.

Immediately before each time signal is broadcast, the error of the transmission apparatus is determined by a chronograph comparison with the standard clocks. The record sheet of this chronograph permits very accurate measurements to the fraction of a second. The continuously changing differences between sidereal and solar time and the error of the sidereal clock are also applied resulting in our mean solar time broadcast being accurate within one one-hundredth of a second.

This comparison and correction is made immediately prior to each broadcast and requires several minutes to complete.

Five minutes before the zero hour and after the transmitting clock has been corrected to mean solar time with the greatest possible accuracy, the operator throws the controlling switch which gives the Naval Observatory direct control over the Navy's high power radio stations at Arlington and at Annapolis. From then on, the operation is entirely automatic.

Every second is broadcast except certain ones omitted for identification signals, and others which act as fingers pointing definitely to the next audible second following the period of silence.

The twenty-ninth second of each minute is omitted and therefore definitely points to the 30th second of each minute. The 56th, 57th, 58th, and 59th seconds are omitted therefore definitely indicating that the next succeeding second, the 60th, is the beginning of another minute. This occurs on the 55th, 56th, 57th, and 58th minutes before the zero hour. On the 59th minute there are no audible "ticks" from the 50th to the 60th second, indicating that after a silence of nine seconds, the next audible tick is the zero hour either midnight, 3:00 a.m., noon, 4:00 p.m., 7:00 p.m., or 10:00 p.m., seventy-fifth meridian time, or Eastern Standard Time.

In order that those listening for the broadcast can distinguish the minute when they tune in for reception, the fifty-first to the fifty-fourth seconds are used as identification signals. If the 51st beat is omitted, the listener will count four more beats before the end of the minute silence occurs, the 52d, 53d, 54th, and 55th beats. This indicates that there are four more minutes to go. If the 52d beat is omitted, the listener can only count three more beats before the silent period, the 53d, 54th, and 55th beats indicating three more minutes to go. If the 53d beat is omitted, the listener can count only two more beats, indicating two more minutes to go, and if the 54th beat is omitted, the listener can count only one more beat and knows that he has only one more minute to go before the zero hour.

This standard broadcast is known all over the world and is religiously listened for in the most remote parts of the globe.

If for any reason, the broadcast is interfered with, it is repeated the following hour.

In addition to our direct control of the two high power stations at Arlington and Annapolis, the Observatory also controls by radio the retransmitting station at San Francisco, and eventually it is hoped that this service will be extended to the east.

During the time broadcasts, automatic chronographic records are made at the Observatory which show the time of the sidereal clock, the time of the transmitting clock, (mean solar time) and the actual time of broadcast by Arlington and by Annapolis.

Immediately after the completion of the time signal broadcast, this record is measured and the difference noted. This gives the time of actual emission by each station. The corrections to the standard clock are then recalculated using star sights taken both before and after the broadcast. Errors are carefully computed and a correction sheet is sent weekly to all those requiring extreme accuracy noting the error on 75th mean solar time of each broadcast of each day. In addition, immediate corrections are sent out to those requiring more rapid service.

DESCRIPTION OF THE TIME CLOCK VAULT—SIDEREAL CLOCKS—COMPARISON OF THE PERFORMANCES OF VARIOUS CLOCKS

The standard sidereal clocks are rated very accurately to sidereal time. They are maintained in a vault under constant temperature and air pressure in order to minimize the effect of changes in either temperature or pressure on the rates of the various clocks.

A new vault is now under construction. It will accommodate seven clocks each on a separate pier and so arranged that no two adjacent pendulums will swing in the same plane. The vault consists of an inner and an outer vault separated by a three-foot air space. The inner vault will be illuminated by flood lights let in through the walls from light boxes in the three-foot air space, exactly as magazines are illuminated on board naval vessels. This will permit cleaning and repairing the lighting apparatus without entering the inner vault.

The temperature control will also be installed in this air space. A periscope to be lowered through the roof of the inner and the outer vaults from the office space above ground will permit visual inspection of the clocks in the vault.

The walls of the outer vault will be continued above ground and the enclosed space will be built as an office for the time service, record rooms, etc. There will also be a sleeping room for the use of astronomers on night watches.

At present there are three clocks made by Riefler in

Germany which are about thirty years old. Also one new Shortt clock made by the Synchronome Company of England and an order has been placed for a second Shortt clock.

A study of the Riefler clock No. 60 during a period of twelve years, 1916 to 1928, showed that its performance could be predicted 10 days in advance with an average error of 0.09 second. One day predictions showed an error of about 0.009 second. The other two Riefler clocks did not perform so well.

Shortt clock No. 38 has been under observation only for a relatively short period. Based on its performance from March 15 to August 12, 1931, its performance could be predicted ten days in advance with an average error of 0.05 second and daily predictions with 0.005 second error. A study of the Shortt clocks at Greenwich Observatory over an extended period confirms these figures. Taking all three Riefler clocks together, it is not possible to predict as well as by the Shortt clock, in other words, the Shortt compares favorably with the three Rieflers combined.

For longer periods, the Shortt clock is considerably better. The Rieflers are all subject to slow progressive changes in rates amounting to a tenth or even a quarter of a second per day in a year. No such change has been evident in the running of the Shortt clock. The Greenwich Shortt clocks show evidence of such a change but to a much smaller degree than the Rieflers.

NEW DEVELOPMENTS—NEW CLOCKS—PROJECTS FOR EXTENSION OF THE TIME SERVICE

The Observatory now has under construction three new clocks, an additional Shortt clock, a crystal controlled clock, and an experimental clock. The crystal controlled clock is being constructed by the Naval Research Laboratory under the supervision of Doctor L. P. Wheeler and Mr. W. E. Bower in accordance with their design which differs from those heretofore in use. The crystal is bar shaped and about four inches long. It has a fundamental frequency of 1,000 cycles per second, and is suspended at its nodes. Condenser plates placed in proximity to its ends, are connected to the input of a vacuum tube amplifier. The output of the amplifier is used to operate a telephone unit, the acoustic output of which is directed at the middle of the crystal, thus sustaining the oscillations. It is claimed for this method that the coefficient of the coupling between the crystal and the vacuum tubes is much less than in the conventional type. The frequency of the crystal is consequently less affected by variations in the tubes.

The crystal oscillator, in addition to serving as a new standard time keeper, will be used for controlling a new automatic time signal transmission apparatus which is being developed at the Naval Observatory. This is being designed for greater accuracy and reduced labor for maintenance.

The experimental clock is being planned by the time service personnel and embodies several new ideas.

In addition the Observatory is planning a more efficient apparatus for retransmission of the Observatory's time signal via San Francisco. If this proves successful, a similar installation will be tried at Honolulu and it may be carried on to a similar one in Guam and later in Manila.

Discussion

For discussion of this paper see page 550.

Time Services of the Telegraph Companies

BY G. W. JANSON[1]

Member, A.I.E.E.

GENERAL

IN the solar time system which forms the basis of the coordination of most human activities, a specified time at a given point is understood to mean a definite position of that point in respect to the sun. Thus, the true solar time at any two places upon the earth's surface not on the same meridian is different at any given instant. In order to avoid the confusion resulting from a large number of time standards, the earth's surface has been considered as divided into time zones and a standard of time arbitrarily chosen for each such zone. The North American Continent is included in seven such zones, the width of each being approximately fifteen degrees longitude or one twenty-fourth of the earth's circumference. In each of these, a standard time is used which differs by one exact hour from that of the adjoining zones and which represents the mean solar time of a meridian passing through it.

It is essential that the indication of time by clocks and other devices within a time zone be kept alike and at a proper relationship to those of other zones and to time as indicated by the sun. This might be done at each point by frequent comparisons of the time indicating devices with determinations of true time made from observation of the sun or other heavenly bodies. Such a procedure would be quite involved and hence for general practise the observations of a selected few places are relied upon as the basis of accurate time for many other points. The results of the determinations of the selected observatories must therefore be accurately and widely communicated to the dependent places and for this a system of electrical time signals is utilized.

The distribution of time signals as described in this paper may be divided into three classes of service. The first of these, commonly known as the "noon beats," comprises the transmission during a three minute period, ending at noon Eastern Standard Time, of a series of electrical impulses at intervals of exactly one second or multiples thereof. These signals originate from the Naval Observatory at Washington and are transmitted to the Western Union and to the Postal Telegraph-Cable Company who further distribute them to telegraph and railroad offices where they are used as a comparison standard by means of which these offices may determine the error in their time indicating or recording devices.

The second service commonly known as the "jewelers beats" comprises a similar transmission throughout the day of a coded series of impulses by which the time of day may be determined to a small fraction of a second. These beats are used principally by jewelers and watchmakers for the purpose of checking and regulating time pieces. Some of this work, for example the regulation of ships' chronometers, requires a high degree of accuracy and hence a continuously available standard of correct time.

The third and largest of these services is the clock or synchronizing service. This comprises the automatic correction or resetting of clocks or other devices which independently maintain an approximately uniform motion. The Western Union Telegraph Company's synchronizing system corrects about 120,000 clocks of which 95 per cent are rented to subscribers and the remainder are in its own service or owned by individuals or firms who subscribe for the synchronizing service which hourly resets the clocks to the correct time.

NOON BEAT SERVICE

The noon beat service which forms the basis of comparison for the accuracy of all other parts of the systems described originates with the Naval Observatory at Washington. Here astronomical observations are made each night when conditions will permit and from these, the error of the three principal naval master clocks is determined. These clocks are of great accuracy, and specially installed so that their rate is not affected by temperature and other variations.

The observatory equipment includes in addition to the three master clocks, two secondary master or transmitting clocks. The rate of these clocks may be altered by magnetic means shortly before it is expected to send signals from the observatory. Adjustments are made to bring these clocks to the correct time as indicated by the master clocks and the correction for their known error.

Signals are transmitted from the Observatory several times a day for five minute periods to various radio stations and communication companies who redistribute them. The signals are always sent during the last five minutes before the exact hour and are made by closing a circuit for a brief period immediately following the end of each second except the following:

29th, 51st, 56th, 57th, 58th and 59th seconds of the 56th min.
29th, 52nd, 56th, 57th, 58th and 59th seconds of the 57th min.
29th, 53rd, 56th, 57th, 58th and 59th seconds of the 58th min.
29th, 54th, 56th, 57th, 58th and 59th seconds of the 59th min.
29th, 51st, 52nd, 53rd, 54th, 55th, 56th, 57th, 58th, and 59th seconds of the 60th min.

The signals from the observatory control a special form of telegraph repeater in the Washington office of The Western Union Telegraph Company and in the

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

Washington office of the Postal Telegraph-Cable Company, so that daily, commencing at 11:57 a.m. Eastern Standard Time, the beats are repeated and transmitted to all of the large telegraph centers. At each of these, the incoming lines carrying the beats are similarly connected to time repeaters which repeat the signals into a number of telegraph circuits covering the territory served by that central office. In this distribution, the beat signals are connected to more than 200,000 miles of telegraph line wires.

The signals indicating the time determined as correct by the Naval Observatory are thus automatically repeated throughout the United States and made available at all points having local master clocks controlling time functions so that these devices may be corrected daily for any error which may have accrued during the preceding twenty-four hour period. All the other distributions of time described in this paper are on a local basis, that is, controlled by a local master clock serving a city or other territory not exceeding a few miles radius.

JEWELERS' BEAT SERVICE

The jewelers' beat service mentioned at the beginning of this paper is quite similar to the noon beats. Each city or local territory in which this service is given is provided with a master clock equipped with the necessary contacts and with auxiliary equipment for transmitting time beats. These signals are transmitted to circuits upon which are connected in series a number of telegraph sounders installed in the offices of the jewelers, watchmakers, and others subscribing for the service.

In general, the code followed for this service differs from that described above for the noon beat signals. The local master clocks are equipped with contacts for sending beats in accordance with a code which divides each hour into five minute periods, the first of which commences at the exact hour, with the exception of a silent minute following the exact hour. Beats or impulses are transmitted after each second except the 29th second and the last five seconds of each minute. During the last minute of each five minute period, the beats indicating the end of the 50th to 54th seconds are also omitted, making the final silent period of ten seconds duration.

CLOCK SYNCHRONIZING SERVICE

The most extensive distribution of correct time carried on by the Telegraph Company is the automatic correction of clocks. Each of these clocks is provided with an electro-magnetic device by means of which the hands may be set to a predetermined time. This mechanism is independent of the motive power moving the clock hands and is thus applicable to practically any of the general design and types of clock mechanism. A large majority of the clocks actually in service in the system described have mechanisms of the spring-driven pendulum-controlled type, provided with a local battery and an electric motor which automatically keeps the driving spring properly wound.

A number of the clock magnets is connected in series on a line wire and all such line wires serving the local territory are carried to a central or control office. Once each hour, there is sent from the Central Office a "synchronizing" impulse which operates the magnets and sets the clock hands to indicate correct time. There is in use a number of methods of distributing the synchronizing impulse so as to make all clocks conform to the correct time, and of insuring against interferencee with the service.

This paper describes the latest of these arrangements, designed for the larger cities, in which contacts on a local master clock control a machine equipped with a large number of contacts, each pair of which connects a line circuit to a source of power at the precise hour. This synchronizing machine is motor driven and as constructed at present, is capable of handling 120 line wires, each of which may connect together groups of approximately 60 clocks. The synchronizing machine is provided with many special features to safeguard the clock service and with adjusting arrangements by means of which the time as transmitted by the machine may be made different from that indicated by the master clock controlling it. This latter feature permits correction for any slight master clock error with no readjustments of that device. It is only necessary to regulate the master clock by means of weights on the pendulum when the accumulated error exceeds four seconds. In this way, frequent regulations and consequent irregularity in the operation of the master clock are eliminated.

Included with the synchronizing arrangements at the Central Office are automatic means for testing the clock circuits. These are embodied in a motor-driven test machine which is started by auxiliary clock contacts at predetermined intervals. When the machine is thus started, it connects successively to each line certain electrical testing circuits which compare that line with a simple artificial line of correct characteristics. The mechanism is so arranged that when a line under test varies considerably from the artificial line, a printed record is made on a paper tape of the designation identifying that line.

The two machines are mounted upon a 22 in. by 26 in. shelf attached to a metal cabinet 26 in. by 18 in. by 81 in. high. This cabinet houses the auxiliary apparatus required in the operation and control of the machines and is provided with a jack panel at which each synchronizing clock circuit is made available for such tests and trouble analysis as may be desired. The switchboard is provided with a volt milammeter and other equipment to facilitate such work. The completed switchboard is shown in Fig. 1.

While the above describes in general the synchronizing clock service, a more detailed description of the clock mechanism, and of the electrical circuits of the synchronizing and testing machines may be of interest.

Clock Mechanism. Fig. 2 shows the mechanism applied to a clock for resetting its hands if the clock is in error when the synchronizing pulse is received.

Regular clock mechanism connected to the shaft *G* causes that shaft to make as nearly one complete revolution per hour as practicable. The shaft is connected through a friction coupling to the double disk *Q* and hence the latter is driven by the clock mechanism but may be moved independently. To this disk is mounted the minute hand of the clock and the gear train driving the hour hand one revolution for each twelve revolutions of *Q*. A lever *D* is so arranged that when the electromagnet *A* is energized its armature *B* causes *D* to strike projections on *Q* and thus move *Q* and the clock hands controlled by it to a definite position; *i. e.*, that corresponding to the exact hour. Normally, the synchronizing lever *D* is locked in the position shown by means of the locking lever *H*, which carries a pin *S* that engages the catch *T* on *D*. This arrangement prevents any current which might be used for testing during other portions of the hour from operating the synchronizing mechanism. At three minutes to the hour, the pin *U* on the disk *Q* engages the lever *H* and moves the locking pin *S* from under the catch *T*. The mechanism is now free to operate when the synchronizing current passes through the magnet *A*. The pin *U* remains engaged with the locking lever until three minutes past the hour, at which time it allows the lever *H* to drop back in position and lock the synchronizing mechanism until the next hour.

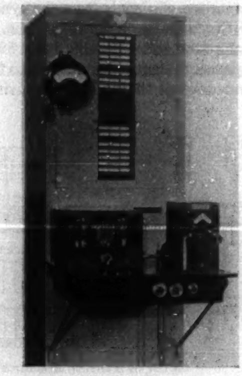

FIG. 1

A somewhat different mechanism is generally used to set the second hand of a clock and that is also illustrated in Fig. 2. The second hand is regularly attached to the heart-shaped cam *R* which is driven through a friction coupling by the clock mechanism. When the synchronizing magnet is operated, the lever *C* is pressed against this cam to advance or retard the second hand to a position indicating the beginning of a minute.

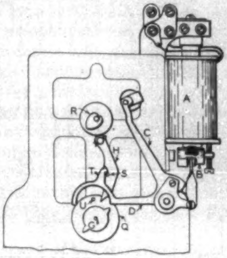

FIG. 2—CLOCK SYNCHRONIZING MECHANISM

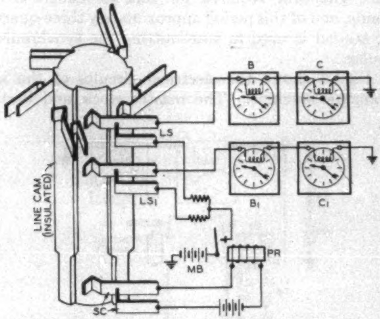

FIG. 3—ELEMENTARY CLOCK CIRCUIT

Synchronizing Machine. The clock magnets are grouped in series on line circuits which are connected to contact springs on the synchronizing machine. Each machine is provided with two cams for closing these line springs and for controlling the application of power for the transmission of the synchronizing impulse. These elements are illustrated in Fig. 3 in which *B*, *C* and B_1, C_1 represent clocks on two lines connected to the springs *LS* and LS_1 arranged for operation by the insulated cam. Around each cam are disposed ten layers each containing six sets of contact springs, the cam thus controlling contacts for a total of 60 lines. One of the cams is also arranged to operate a pair of "synchronizing contacts" shown in Fig. 3 at *SC*. Once each hour, the master clock causes the cams to revolve through one-third of a revolution. As they do so, each set of line springs is closed and then restored to its normal condition except that they rest upon a similar portion of the cam 120 deg. farther advanced. The movement of the cam also closes the spring *SC* which through the operation of the power relay *PR* connects the line wires to a source of operating current *MB*. It should be noted that the raised portion of the cam which passes under the springs *SC* is shorter than that under the line springs. This insures the line circuits being closed before power is applied and that they remain closed until the power relay has been deenergized and has removed the power connection. In practise, a number of power relays is used, each controlling the current to a group of lines varying in number from 12 to 30, depending upon the potential used.

FIG. 4—ELECTRICAL CIRCUIT OF SYNCHRONIZING MACHINE

The cams are driven by an electric motor through gear trains so controlled by a master clock that once each hour the cams turn through one-third of a revolution. The time required for this movement is four seconds, and of this period approximately three-quarters of a second is used in transmitting the synchronizing impulse.

Fig. 4 shows the electrical circuits of the synchronizing machine. The master clock and battery clock shown control the machine in transmitting the impulses. At five seconds before the hour, the battery clock contacts close and remain closed until five seconds after the exact hour. These contacts through suitable relays connect the machine to the source of operating current for the clock line circuits. The master clock contact shown as Contact 2 closes at approximately 15 seconds before the exact hour and opens at five seconds before the exact hour. The closing of these contacts starts the machine in operation and sets the various control parts to a correct initial position. Through suitable clutch mechanisms, the opening of Contact 2 causes a timing arm to revolve and connect to contacts on a timer table. The timer table contacts control a "line clutch" mechanism so that during the interval between the closing of the two pairs of these contacts, the cams are turned and transmit the synchronizing signal. By manual adjustment of the position of the timer table contacts, the time relation between the connections to them and the opening of Contact 1 may be varied to compensate for errors in the master clock.

FIG. 6—CIRCUIT OF TESTING MACHINE

Testing Machine. In Fig. 5 is shown in heavy lines a schematic representation of a clock circuit and in light lines the electrical elements of the testing arrangement used in checking the quality of the clock circuit. The tap resistance *TR* is fixed at approximately one ohm per volt of operating potential of the main battery *MB*, while resistance *LR* is selected so that the current during the synchronizing impulse will be 250 milliamperes. The resistance from *A* to *G* will therefore be the same for all circuits operating from a given potential. A fault on the clock circuit would either decrease or increase this resistance value. The testing arrangement of Fig. 6 is designed to indicate when such a change from the normal resistance exists.

The center point *X* of a differentially wound relay is connected to the testing battery *TB*. One winding of the relay is connected to the line at *A* and the other winding is connected to the artificial line resistance *ALR*. Resistance *ALR* is adjusted to equal the nominal value which should exist for all circuits operating at the potential of the main battery *MB*. If the resistances in series with the two windings of the differential relay are equal, the current flowing from the battery *TB* divides equally and the relay will not be operated. Should the line resistance vary from that of the standard *ALR* as a result of a ground, open or other fault, the currents in the two relay windings will be unequal and the relay will operate the printing magnet.

Fig. 6 shows schematically the electrical circuits of the testing machine. Once each hour, the motor controlling this machine is started by the closing of the clock contacts. A brush shown at A_1 moves spirally and contacts with the line studs L_1 while brushes A_2 and A_3 contact with studs L_2 and L_3. In making these connections, each line is connected to one of the differential relay windings and thus compared with the artificial line or standard. If, as a result of an improper line condition, the relay is operated, the printing magnet causes an impression to be made upon a paper tape to indicate the position of the Brush A_1 at the time the printing magnet has operated. This identifies the line in trouble to an attendant who may then make the necessary tests to determine the nature of the fault.

SUMMARY

The proper distribution of time information requires a continuity of accurate service. This the systems described aim to accomplish by the subdivision of the distribution into local areas each entirely independent of all others. The equipment in each area is capable of rendering an accurate time service to subscribers in that area for extended periods without assistance from other sources and by the nationwide dissemination of standard signals may be held to a negligible variation from true time. The equipment and operating methods are such that troubles occurring within the area will produce a minimum of interference with the accuracy of the distribution within that area and will be promptly indicated so that they may be remedied.

Discussion

For discussion of this paper see page 550.

Synchronous Electric Time Service

BY H. E. WARREN[1]

Associate, A.I.E.E.

BEFORE the beginning of the present century, there were a few individuals who realized the possibility that commercial alternating current might be used in some manner, by means of its recurring pulsations, to measure time; but dreams of this nature did not materialize in practical performance.

Up to 1916 there was no commercial a-c. system in existence in which generator speed was regulated with sufficient accuracy so that the current could be used for the purpose of indicating time by means of synchronous clocks. At that time two devices were brought out which in the succeeding years made possible commercial a-c. time service.

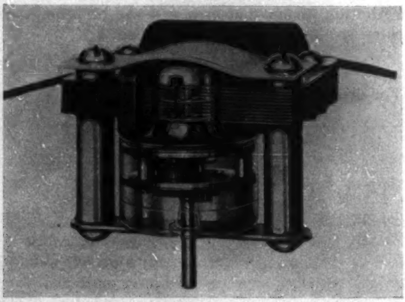

Fig. 1—Type B Telechron Motor and Gear Train

The first of these devices was a self-starting synchronous motor which utilized residual magnetism to enable a rotor to start and run at synchronous speed. This type of motor differs from all the common forms of a-c. motors in that eddy currents, induced either in the mass of the rotor or in some form of winding upon the rotor, are not utilized to start the rotor from rest. In place thereof, the rotor is made of such permanent magnetic material and is so proportioned with respect to the field that remanent magnetic poles are set up in the rotor material by the a-c. magnetism of the field in such a manner as to cause the desired motion. Such a motor is sometimes known as a hysteresis motor. Fig. 1 shows a phantom view of a recent model of this motor.

The hands of a clock were connected by a gear train with the first of these self-starting synchronous motors and this clock, supplied by current from the local electric light system, was compared with standard time, at intervals, over a period of several weeks. The new motor-driven clock proved to be a very inferior timekeeper, developing daily errors as great as five or ten minutes, thus proving the need of greater accuracy in the average frequency of the power supply if it were to be used for timekeeping.

By observing these daily errors, it was easy to compute the average value of the system frequency. There are 1,440 minutes in a day and the gearing of the clock was such that, if the frequency had been exactly 60 cycles, there would have been no time error. A 1 per cent error in average frequency (0.6 cycles at 60 cycles) would mean 1 per cent error in the time of the clock, which amounts to 14.4 minutes in a day. The actual computed error in the average frequency, as determined by these observations, is shown in the upper curve of Fig. 2 which was originally published in the article "Clocks in the Field of Electric Light Appliances" in the *Proceedings* of the N.E.L.A. for 1917.

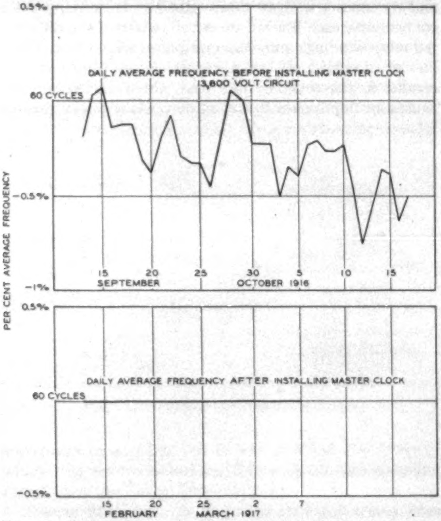

Fig. 2—Daily Average Frequency Before and After Installing Warren Master Clock

The second device consisted of an indicating instrument that would show to a generating station operator, directly in terms of time, deviations of average frequency from standard. Guided by this instrument an operator could so regulate the speed of his generators

---

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

as to maintain such small deviations from standard average frequency that the alternations could be used to measure time for all ordinary commercial purposes.

Fig. 3 shows the dials of a type of master clock which is in common use. The large dial in the center has two hands, one colored black and the other gold. The black hand makes a revolution on the dial every five minutes; its rate of motion being regulated by an accurately adjusted pendulum beating seconds. The gold hand is driven by a gear train directly from one of the Telechron self-starting motors. The gear ratio is such that, when the average frequency is correct, this hand will also make one revolution in exactly five minutes.

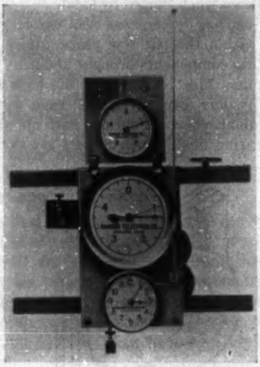

Fig. 3—Operating Dials of Type A Master Clock

The two hands are started off together. So long as the average frequency remains correct, they will keep together and there will be no visible angle between them. An error in the average frequency will cause the gold hand to move slightly faster or slower than the black hand and they will become separated. The angle of separation will be a direct visible measure of the error in the integrated alternations, which may be conveniently called the system time. If the gold hand is ahead, this will show that the system time is fast; if behind, that it is slow.

An error in the average frequency as small as 1/60th of a cycle will cause a spread of one second between the two hands of the master clock, in one hour. If such an error continues, the spread will continue to increase as time passes. The accuracy of the indication is limited only by the time keeping precision of the pendulum itself. When carefully regulated this is better than one second per day, or an absolute precision of about one part in one hundred thousand.

When the operator, at the generating station which is regulating frequency, adjusts the turbine governors from time to time so as to keep the black and gold hands of the master clock together, he automatically causes all other synchronous motor clocks on the same system to keep correct time. The lower curve of Fig. 2 shows the great improvement in the average frequency value which was obtained after the first master clock installation.

The standardization of average frequency is of great value to the power companies in the following ways:

1. By improving the service furnished to manufacturing establishments, ensuring more uniform speed of motor-driven machinery and as a general result assuring the quality of the product.

2. By facilitating interconnection with other power companies which have correspondingly standardized their frequency.

3. By enabling power companies to use synchronous motor movements in their maximum demand meters and graphic recorders, thereby obtaining more accurate and synchronized records at lower cost of maintenance.

Before master clocks were available, the inherent errors in frequency indicators were sufficient to handicap operators on interconnected systems in their efforts to equalize the frequency preparatory to synchronizing the two systems, and to lead to controversy as to the true value of the frequency after the two systems were synchronized.

Master clocks have been generally adopted by the power companies of the United States for the purpose of regulating frequency. At the present time, it is estimated that the regulation of the current to over 90 per cent of the consumers' meters in this country is guided by these master clocks.

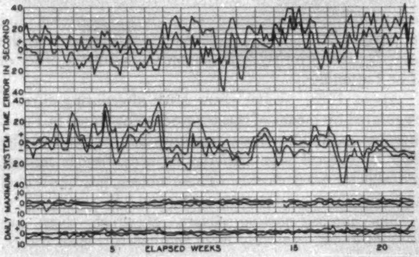

Fig. 4—Maximum Daily System Time Errors of Four Large Power Systems

The accuracy which may be expected at present from a synchronous electric clock is indicated by the records shown on Fig. 4. The records shown on this chart are taken from four typical very large interconnected systems east of the Mississippi River. The ordinates of the curve in each case are seconds deviation from standard time, and the abscissas weeks over a period of five months. The solid line through the center of each curve represents standard time, and the two points plotted for each day at the top and bottom of the band represent the maximum range of the deviations from standard for that day. The widest deviations shown are 44 seconds fast or slow, which means that a synchronous clock on these systems set absolutely accurate with standard time did not, through the period plotted, indicate incorrect time more than 44 seconds fast or slow. The records of the two systems which show the smallest departure of standard time indicate that a clock operating on these systems would never be more than 9 seconds fast or slow. There are few uses of time which justify higher accuracy, and even the worst of these records is far superior to that of previous types of commercial clocks.

Some power companies throughout the country may be giving better than the best time service indicated on this chart. Probably there are some permitting wider variations. Practically all power companies, however, are giving sufficiently accurate frequency regulation to provide far better time on synchronous clocks than on commercial clocks previously available.

All factors in power system development are tending to require continued improvements in frequency regulation. As a matter of fact the very large interconnected systems have so much momentum stored in rotating equipment (generators, motors, etc.,) that they will give, when properly adjusted at the beginning of a flat load period, almost perfect time with no adjustment of governors for speed. Governor adjustment is necessary, however, over the irregular portions of the load curve and much work is being done at present to divide the burden of this regulation on large interconnected systems between the various power companies by the use of automatic frequency control to supplement the master clocks. When perfected and applied these instruments will undoubtedly reduce the system time error to insignificant values of the order of 1 or 2 seconds.

About 1928, twelve years after alternating current regulated by means of master clocks illustrated in Fig. 3 became available, there appeared on the market the first of several new varieties of synchronous motors suitable for use in clocks. These motors may be divided into two classes; non-self-starting and self-starting.

The *non-self-starting motors,* of which there are several kinds, generally have toothed soft-steel rotors. The usual stator construction is bi-polar with teeth on each pole corresponding to the spacing of the rotor poles. In all multipolar motors of the common varieties the speed is found by dividing the number of current alternations per minute by the number of rotor or stator poles. In nearly all cases no attempt is made to introduce a rotating component into the field. A common arrangement of rotor and stator is shown in Fig. 5. On account of the difference in magnetic reluctance between rotor positions, where the poles do or do not correspond with the stator poles, a strong reactance torque exists when the rotor is at rest. This tends to prevent the rotor from starting; but when running at synchronous speed, tends to keep it at that speed.

It is somewhat difficult to spin such a rotor by hand so as to cause it to lock into synchronism with the alternating field, unless some means are provided which will permit a sudden phase shift of the rotor poles as the rotor speed passes through its synchronous value. Among the satisfactory schemes for accomplishing this result are the use of loosely coupled fly-wheels on the rotor shaft or spirally arranged rotor poles with means for the axial shifting of the rotor in the field. Mechanical launching devices are also sometimes used automatically to bring the rotor up to approximately synchronous speed when started by hand.

The *self-starting synchronous clock motors,* which have appeared within the last few years, utilize a-c. fields with rotating components brought about by the use of shading coils. Most of these motors have multipolar rotors with some form of squirrel cage winding or a copper element wherein Foucault currents are induced by the rotating field. Such motors get their starting torque, like ordinary induction motors, through the reaction of the Foucault currents in the field. Synchronous driving torque, in these varieties of self-starting motors, is produced by polar projections of the steel rotors or by a separate polar element loosely coupled to the rotor shaft. One variety of the recent self-starting synchronous motors utilizes remanent magnetism for starting and for synchronous operation.

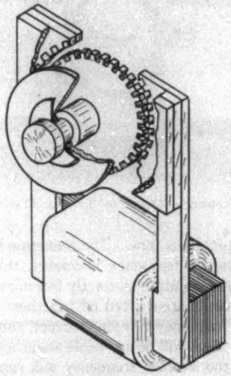

FIG. 5—NON-SELF-STARTING SYNCHRONOUS CLOCK MOTOR

Any of the rotors heretofore described may be used to drive the hands of a clock through a simple train of gears. Two forms of such gear trains are in common use, one composed entirely of spur gears and the other utilizing worm gears and worms. On account of the greater efficiency of transmission, a spur gear train is better for large clocks but for small clocks other mechanism is satisfactory. Frequently, the high-speed gears of a spur gear train are made of non-metallic material so as to run more quietly and the motor or the whole clock movement is usually mounted on cushioning material so as to reduce the a-c. hum. Some clocks are much quieter than others depending upon the rigidity of the field laminations and the design of the moving parts.

Any one of the motors mentioned is adequate to drive the hands of a clock dial 12 in. or less in diameter. The actual output required for this purpose is exceedingly small. If the clock hands are balanced and the gear train is fairly efficient, not more than one-twenty millionth of a horsepower is needed for a 12 in. dial. The power output of the various motors ranges from less than one-millionth of a horsepower to more than one-ten thousandth of a horsepower. The larger amount has been found adequate to drive tower clocks ten or twelve feet in diameter. The power output of these motors seems exceedingly small as compared with commercial motors which are used for other purposes but it is, nevertheless, fully adequate for this time keeping duty and is many times greater than the power of ordinary spring clock motors.

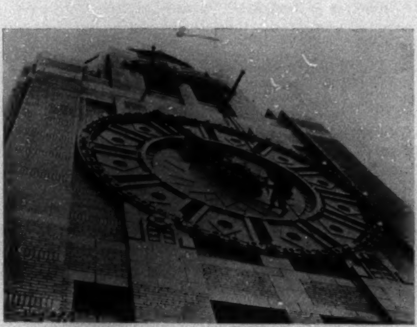
The electrical input to these motors is generally in the neighborhood of two watts, but as the power factor is low, the volt amperes will vary from three to six. Obviously, the efficiency of these motors is very low indeed, amounting to a fraction of 1 per cent. However, the power used is so little (17 kw-hr. per year or approximately $1.00 worth) that this feature is of minor importance.

Most synchronous motor clocks are provided with some form of indicator visible through a small hole in the dial. In clocks which are not self-starting, this indicator shows by its continuous motion that the clock is in operation. After an interruption in the current, the motion of the indicator stops permanently. In self-starting motor clocks of the Telechron brand, the indicator, back of the dial, shows a steady white target as long as the current flows. This target changes to red and so remains after an interruption in the current supply, although the clock, of course, starts and continues to run as soon as the power is restored.

Inasmuch as most kinds of synchronous motor clocks will either stop permanently or show errors after current interruptions, it is reassuring to know that system interruptions are rare in our thickly settled districts. Often, these clocks continue to show correct time within a very few seconds for many months, even for years. In order to provide against the rare stopping of the hands because of interruptions, clocks have been available for many years which have auxiliary spring movements. These movements appeared more necessary in the beginning before alternating current service had become as reliable as it is today.

The successful operation of synchronous motor clocks is quite independent of certain influences which are detrimental to other clocks such as level position, vibration, and ordinary temperature variations. Extreme temperatures near zero fahrenheit will stop some kinds of clock motors, but other varieties will operate well below zero.

Application of these small clock type synchronous motors to many devices and instruments has been going on ever since these motors became available. The first users were the power companies themselves who had many instruments and meters, especially those of the maximum demand type, which required time keeping elements. The spring clocks, which had been used for these purposes, were inaccurate, troublesome, and costly to maintain. This was especially true because they needed frequent winding and were often located at distant points. The instrument load was sometimes too great for a spring clock to handle with accuracy. As soon as the motors were substituted for the spring clocks there was a great gain in accuracy and reliability and the costly winding was eliminated. It then became possible to redesign the instruments so as to give still better performance.



Pacific & Atlantic Photo, Inc.

FIG. 6—DIAL OF LARGE SYNCHRONOUS TOWER CLOCK

Gradually, nearly all the makers of instruments began using synchronous motors in place of spring movements until the list of such motor-driven instruments is a nearly complete catalog of devices in which the measurement of time is involved. The largest class of these motor-driven instruments is perhaps the graphic recording type. The load of driving a paper chart, especially of the strip type, is very great for a spring clock, but comparatively trifling for a synchronous motor. Moreover, the motor can handle a roll of paper so as to make a continuous record for weeks or months without regard to winding. There are also many kinds of instruments which do not make a record but serve to control or actuate, and synchronous motors have advantageously been incorporated into certain forms such as time switches, temperature controllers, traffic signals, etc.

There is a large and important class of timing devices exclusive of ordinary clocks. Among them are numerous kinds of time and cost recorders, program machines, time stamps, etc., wherein synchronous motors have gradually been replacing spring clock movements. This change has made it possible, in many cases, to eliminate local master clocks, batteries, and expensive wiring.

In building installations, where Telechron clocks, or timing devices driven by Telechron motors, are numerous it is customary for the customer to provide a so-called "resetting device" or else a duplicate source of alternating current energy to guard against the effect of interruptions in the supply of current. In all such installations, a separate wiring system is used and this is connected with the public service system through a suitable switchboard. The resetting device automatically measures the duration of an interruption and, after the current is restored, applies higher frequency or otherwise speeds up the clocks until they are again correct.

The problem of driving very large tower clocks by means of self-starting synchronous motors is much less difficult than that formerly involved in the use of conventional pendulum tower clock movements. It is necessary, of course, for the gears and shafts to be very strong because the stresses due to the great weight of the hands and the pressure of the wind are rather high. Fig. 6 shows a tower clock movement installed on the Williamsburgh Savings Bank at Brooklyn, N. Y. where each of the four dials is 26 ft. in diameter and the hands alone weigh 700 lb. per pair. The hour hand sleeves of this clock are of steel and their outside diameter is 4 inches. The power required to drive these hands during a heavy wind is less than 0.001 hp. The motors used have a very large surplus power margin.

The use of synchronous motor clocks and timing devices has increased since its conception in 1916 with extraordinary rapidity, especially during the last few years. According to estimates more than one million two hundred thousand synchronous motor clocks were sold during 1930.

There seems little doubt that, during the coming years, spring and weight driven clocks will be replaced in large measure by the new a-c. timekeepers, which have proven greatly superior in every important respect.

The author wishes to express in this paper sincere appreciation of the generous aid which has been given by numerous executives and engineers to promote the attainment of commercial time service by means of alternating current—especially those men with far sighted vision who realized the possibilities before there were any actual results.

He would also express thanks to Mr. George M. Keenan, Superintendent of the Pennsylvania-New Jersey Interconnection, who has cooperated in the preparation of this paper.

L. S. Harrison: This discussion presents an important development in the particular field of institutional electric time systems—where a multiplicity of clocks is designed to influence the coordination of activities in schools, hospitals, office buildings, railroad terminals, industries, etc. It is a master clock system which hourly supervises the uniform agreement of electric secondary units.

This system which has had widespread application during the past seven years combines certain basic principles of practical timekeeping in a unique manner. The most reliable means of obtaining commercial accuracy is with a high grade 60-beat pendulum regulator. A well designed unit, properly mounted and free from vibration is capable of rating within two to three seconds per month of standard time without resetting, or an error of approximately 1 in 900,000.

The practise of all of the best known systems of electric clocks to employ, somewhere in the system layout, a 60-beat master regulator, confirms this basic necessity of time system engineering. However, the high accuracy of a master clock does not by itself, assure the successful transmission of system time to the various individual secondary time indicators because to complete its function as a time governor, a master regulator must do two things:

1. It must provide an electrical operating medium to propel secondary clocks at an accurate constant rate of advance, and
2. It must transmit to each secondary clock, periodically, a point origin of time on which to establish such constant rate.

It should be borne in mind that secondary time units are not of themselves, clocks; they cannot keep time by themselves but must depend upon an uninterrupted supply of accurately timed pulses and they, hence, inherently reflect as any other meter reflects, conditions in everything which may contribute to or affect their operation; yet these secondary clocks are the real points of utility in the time system and the medium through which the master clock delivers its service.

Further, any clock indicator which depends initially for its timekeeping quality on original setting by hand, obviously does not receive its accuracy from the master clock and cannot be said to do so.

The master clock, which is automatically self winding, transmits its own accuracy over a wiring system wholly devoted to time service transmission to the secondary timepieces both as to rate of advance and as to a point origin of time by means of a periodic time check.

The secondary units are designed electrically to sense their own agreement with system time once an hour and automatically to accept only the exact required number of driving impulses during the hour. These secondaries may be in the form of devices for signaling and recording of time as well as for indicating.

Since its introduction in 1924, this system has been placed in use by large numbers of schools, colleges, banks and office buildings, and industries throughout the United States and Canada. Three outstanding recent installations are the Pennsylvania Railroad Philadelphia Terminal Development, Cincinnati Union Terminal and the Cleveland Union Terminal Group.

A short description of this system is placed on record for reference as follows:

A description of the Hourly Supervised Electric Time System is quite readily grasped when two of its operating conditions are laid down, namely:

1. Each secondary clock (Fig. 1) individually connects itself to the supervising circuit at the 59th minute on its own indicating dial, permitting it to sense its own position with the correct system time.

2. The master clock shown in Fig. 2 provides supervising also during the last minute of the hour by a simple manipulation of the circuit. This supervision, being supplied for variable differences in error, must be handled over two of the three wires in the system, as follows:

(a) On one wire a suspension of impulses for a period of ten minutes before, so that any fast secondaries may be retarded which may have arrived at the last minute of the hour point ahead of the master clock.

(b) On the other wire extra impulses are supplied, during the last minute of the hour, in order that slow secondaries may be stepped ahead.

All units which are on time, are of course, in perfect step with the master clock and therefore do not partake of any of the effects produced by the above supervision. The third wire is a common return.

Philip Sporn: A reading of Mr. Warren's very interesting paper is likely to give the impression, particularly to one who has but a passing acquaintance with the subject, that the question of frequency control on the part of the operators of large power systems is a rather simple affair, involving, as it does not, very little more than the use of a master clock, and that such practise is very beneficial in the operation of a power system. Such, of course, is far from the case; I would, therefore, emphasize some of the dark shadows in the picture in order to give a representation more nearly in accordance with the facts. In connection with Fig. 2 of the paper there is shown a graph of daily average frequency before and after the installation of a master clock. It ought to be pointed out, however, in this connection that while a master clock permits the speeding up or slowing down of system frequency after a certain period has elapsed and the error had been allowed to accumulate, that the straight line curve does not truly represent system frequency.

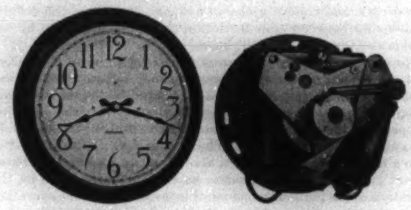

Fig. 1—International Secondary Clock and Movement

Nor is the very jagged and irregular line typical of what can be done without the use of a master clock. The fact of the matter is that during the period covered by the upper curve in Fig. 2, the frequency meters available were of such a crude nature that the results shown are about all that could be expected. On the other hand, the use of a modern frequency meter with its high degree of accuracy without any master clock whatsoever could be made to give substantially as good an average time curve as is indicated by the lower curve in Fig. 2 of the paper. I think it is worth while stressing this because otherwise we may get the old familiar *post hoc, ergo propter hoc* train of reasoning started in connection with the very complicated problem of frequency control and we all know the subject is complicated enough as it is without having to encounter that.

In Fig. 3 is shown a frequency chart taken over approximately 12 hours on our middle western interconnected system in June 1925. A rough examination of the chart will indicate that the *instantaneous* frequency is pretty ragged. At the same time it will be noted that at no time during the 12 hours has it been worse than ½ cycle plus or minus the normal of 60 cycles. It will also be seen that the average frequency is substantially perfect, or if it is not, over this 12-hour period, there would be no difficulty by governor manipulation, say over the 24-hour period, to bring it to perfection, as far as *average frequency* is concerned without in any way altering very much the characteristic of the frequency curve.

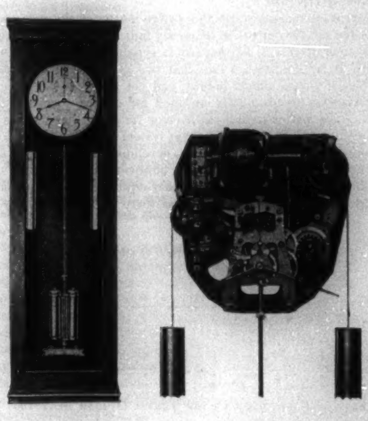

Fig. 2—International Master Clock and Movement

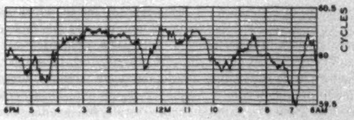

Fig. 3—Frequency Chart Taken in June 1925

Showing excellent average frequency but wide variations of instantaneous frequency

This again is shown because of the claims made in the paper by Mr. Warren that the standardization of average frequency is of great value to the power companies in the ways enumerated:

1. "By improving the service furnished to manufacturing establishments, ensuring more uniform speed of motor-driven machinery and as a general result assuring the quality of the product."

It will be seen from Fig. 3 that so far as giving good service to processes requiring accurate speed, the frequency represented by Fig. 3, although having excellent average characteristics, is decidedly unsuitable and offers no improvement over some other frequency that might have the same characteristics, but which might be floating above or below the 59-cycle line as a base.

2. "By facilitating interconnection with other power companies which have correspondingly standardized their frequency."

Again referring to Fig. 3, it will be noted that a frequency of the type shown there is not adequate in a large interconnected system although again it may be perfect from an average frequency standpoint. The attempt to regulate frequency to make satisfactory interconnection is much more complicated and brings with it a train of many other problems, some of which will be mentioned later.

3. "By enabling power companies to use synchronous motor movements in their maximum demand meters and graphic recorders, thereby obtaining more accurate and synchronized records at lower cost of maintenance."

An examination of Fig. 3 will again show that a considerable error can be introduced in the timing of devices utilizing the frequency of the type indicated there, even though the average frequency is perfect.

Mr. Warren again states that before master clocks were available the inherent errors in frequency indicators were a handicap in system operation, particularly in synchronizing different systems. It is, of course, a fact that two systems can have their *average frequency* almost perfect, and yet at the instant of synchronization be absolutely unsuited for coming together. The fact of the matter is that the average frequency has nothing to do with system operation, but that system operation was greatly facilitated and improved by the development of accurate frequency indicators. It is admitted, however, that it is highly desirable to maintain average frequency equivalent to the nominal frequency of the system as long as there is the slightest claim with regard to constancy of frequency. A master clock along with a time deviation recorder is, of course, very desirable as a means of checking the accuracy of the frequency recorders.

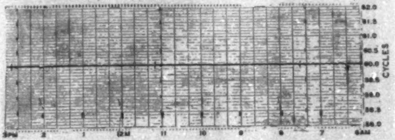

Fig. 4—Frequency Chart Taken During May 1931

Illustrating to what extent instantaneous frequency variations can be reduced

Mr. Warren is, of course, on solid ground when he states that the factors in power system development are tending to require continued improvements in frequency regulation. These factors, however, it should be pointed out, are totally independent of and have no relation to the problem of supplying time and it is doubtful whether the advantages of being able to supply correct time would pay for the difficulties that are involved in maintaining such close frequency. He is not right, however, in saying that very large interconnected systems, because of the heavy momentum, etc., give almost perfect time with no attachment of governors for speed. In Fig. 4 there is shown a frequency chart taken on the same system which furnished the data in Fig. 3, the difference being that it was taken approximately 5 years later. It will be noted that the instantaneous frequency here is almost perfect, having a maximum deviation of approximately plus or minus 0.03 cycles. However, it was not obtained by merely bringing together a large power system and letting it run in parallel after the governors had been adjusted.

In Fig. 5, for example, there is shown a typical loading on one of the tie lines of the particular system tying together two large portions of it during a day when frequency of the order given in Fig. 4 was obtained. It will be noticed that over this particular line within a period of less than 2 hours this tie-line had its load increased from zero to about 95,000 kw., back to zero again with an actual reversal of flow, then up again to approximately 110,000 kw., and down to 20,000 kw. It is obvious that this particular line, in so far as it was intended to function as a steady deliverer of power somewhere close to its theoretical limits, was vitally handicapped by what it was doing in the way of maintaining system regulation so that a frequency shown in Fig. 4 could be maintained.

A more definite relationship between tie-line loading and time deviation on an interconnected system is shown in Fig. 6. It will be noticed that during the 2-hour period, the time deviation from true time was at no time greater than approximately 2 seconds, yet that involved carrying the tie-line through several very erratic and violent cycles of loading. Note, too, the definite relationship between time deviation and load picked up by the tie-line and furnished to the system:

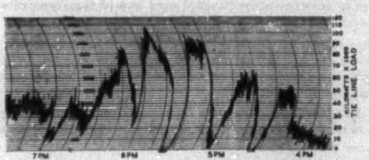

Fig. 5—Typical Example Showing the Effect of Close Frequency Regulation on the Loading of Tie-Line Connecting the Regulating Station to the System

For example, during the period from 5:00 p. m. to 5:20 p. m. load was coming on the system rapidly and the frequency control station was picking up this load as indicated by the tie-line chart in order to maintain frequency. At about 5:20 the upswing stopped and the regulating station backed off about 70,000 kw. in a matter of some 10 minutes. The process was again reversed at even a more rapid rate between about 5:40 and 5:50 p. m. These violent swings in load, of course, have their repercussion on the operation of the plant from which this tie-line is fed and operation under these conditions is not at all a simple matter. For that matter the entire problem of frequency regulation on an interconnected system is highly involved both from a technical and from an economic standpoint. It is important, therefore, that the impression be not allowed to remain that frequency regulation is rather simple; nor that it becomes more simple as more systems are thrown together in parallel; and that the mere installation of a master clock of the type shown in Fig. 3 of the paper will do the trick.

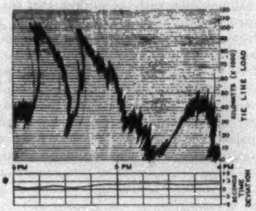

Fig. 6—Typical Case of Power Transfer Across a Tie-Line as a Result of Holding Accurate System Time

Time service should be a logical by-product of system operation; at the present time it appears safe to say that the ultimate method of operating large interconnected systems will be facilitated by extensive use of automatic frequency control devices and that it will be possible to obtain very accurate time service from such systems.

Considerable use has been made of synchronous motor clocks in indicating type and in round chart type demand meters, as brought out in Mr. Warren's paper and this has effected considerable economy and increased reliability in the use of these meters. There is, however, a need at the present time for a synchronous motor clock of sufficient power to drive the timing device as well as the reroll device in strip chart instruments. Some use has been made of synchronous motors in strip chart meters to date, but in practically all cases either an additional motor or a spring is used for the reroll. It is obvious that to replace these two units with single synchronous motors would simplify the construction and considerably lower maintenance. Such a device would be applicable to strip chart demand meters, wattmeters, ammeters, voltmeters, etc. In the case of voltmeters, it would probably be advisable to incorporate some type of carry-over device in order that interruption and duration of interruptions would be properly indicated on the chart.

R. J. Wensley: It is interesting to note that the first interest displayed by the central station industry in synchronous timekeeping was in the use of such methods for the integration of demand against definite time intervals. Such devices began to come into use some years before the distribution of time as a service was instituted by the power companies. As each demand interval was short, usually 15 or 30 minutes, and as the errors were not cumulative the variance from true time over the 24-hour period found in the frequency of all power systems did not affect the commercial application of such devices.

As Mr. Warren's paper is historical in character, it is perhaps in order to add a few comments to complete the historical review of the devices used in synchronous timekeeping. As the motor is the main problem in the secondary clocks, the various classes of motor and the origin of each are of some interest.

Self-starting synchronous motors suitable for clock application are of several varieties:

1. Hysteresis motors, fully synchronous.
    - (a) Smooth rotor hardened material.
    - (b) Toothed rotor softer material.
2. Reaction type, fully synchronous.
    - (a) Phase split by resistance.
    - (b) Phase split by capacitance.
3. Sub-synchronous motors.
    - (a) Two magnetic circuits and rotors.
    - (b) One magnetic circuit, two rotors.
    - (c) One magnetic circuit, one rotor.

Class 1 is the oldest as the smooth core hysteresis motor depending on the remanence of a hardened rotor was quite completely described by Nikola Tesla in 1887. The toothed core hysteresis motor depending on the reluctance of the slots for its synchronous characteristics first shows in the patent granted to Durfee, of Rochester, New York, about 1910.

Class 2 is so well known as to hardly need comment. The use of phase splitting capacitors and resistances to accelerate induction motors with salient poles to synchronous speed dates from about 1900. This type of motor has not been used to any great extent for timekeeping, though it is not at all impossible to design a motor of this type that would be suitable for some varieties of time service.

Class 3 dates back to 1890 when Elihu Thomson described a synchronous motor with an eddy current disk tending to run at high speed, while toothed magnetic structures on the rotor, acting as a magnetic escapement prevented operation above synchronous speed. Sub-synchronous motors are all of this type, differing only in the details of construction. Each of the three types listed consists of an induction element of higher speed characteristics and a magnetic escapement to determine synchronous speed. All of these types have the advantage of slower speed of rotation for a given size of motor. To counterbalance this advantage is the rather critical nature of the design due to the necessity for accurate balance between the induction and synchronous elements.

Mr. Warren mentions the difficulty he experienced in persuading the central stations to agree to frequency regulation. It is very interesting to note that the first inventor to file an application in this country on a complete timekeeping system was Mr. A. F. Poole, who, in 1914, filed on a system comprising a master clock regulator and secondary clocks with synchronous motors. Mr. Poole tried to bribe the power companies by showing a resistance connected in parallel with the secondary clocks to increase the energy consumption. It is very fortunate that the power companies did not need this added inducement even though the problem is not simple as has been quite well covered by Mr. Sporn in his discussion.

It might be well to mention at this time that the usual power system is not regulated with sufficient accuracy to permit of the use of synchronous timing of extremely short intervals. The momentary variation may amount to as much as a tenth of a per cent or more. This error would be too great to permit of the calibration of fine watches by stroboscopic methods using central station frequency as a standard. Many such problems are presented to the manufacturers and of course must be refused.

W. A. Dudley: Mr. Janson has described various time services which the telegraph companies furnish to their subscribers, and in this connection it may be well to mention another important time service which these companies provide for their own purposes.

Synchronized clocks identical with those furnished to subscribers are provided throughout the several operating rooms and offices of the telegraph companies and usually one or more of the clocks in each office is provided with cam-operated contacts which, through suitable relays, are used for the control of timing and dating stamps. The stamps are magnetically operated in equal steps to position type wheels for printing the year, month, day, meridian, hour and minute, and in some cases fractions of minutes. The principal use of the stamps is for timing of messages but they are also used for stamping employees' time cards and other supervisory purposes.

Since all of the time stamps throughout an entire telegraph system are controlled from clocks which are part of a synchronized time service as described by Mr. Janson, it may be seen that the timing of messages at all offices of the system will be on the same basis, and will thereby provide an accurate means for controlling and checking speed of service.

J. C. Wilcox: Mr. Janson's paper very ably outlines the technical characteristics of the equipment used to transmit Naval Observatory time beats to master clocks and master clock correcting signals to subscribers' clocks. As all of these subscribers' clocks are equipped with a special type of self-winding movement particularly adapted to the maintenance of a continuous correct time service, I would enlarge on that part of Mr. Janson's paper which refers to the movements, and give some further idea of their construction, use, and application.

First and foremost stands the fact that these clocks are independent operating units. They do not depend on any outside energy for operation. They are spring-driven and pendulum-operated. A motor automatically winds the main spring once each hour and maintains a constant tension on the main spring to give accurate pendulum control. Clocks running independently can be regulated within three or four seconds in twenty-four hours. To check for any variations, however, they are synchronized every hour by the Telegraph Company's master clock. If connecting line should be open for any reason and the synchronizing signal not received the clocks continue to operate continuously and within good commercial limits until the next signal brings them to time. Their outstanding feature is their ability to operate continuously and accurately regardless of outside line interruptions.

This characteristic makes them particularly desirable for use in commercial and transportation fields. In New York we find every railroad and subway system using self-winding clocks in their stations and dispatching headquarters. The largest installation is in Grand Central Terminal where over 1,000 units operate under the control of a central master clock which is checked daily with the noon time beats. The synchronizing line not only covers the terminal proper but extends as far out as Harmon, a distance of thirty miles.

The Pennsylvania Terminal has a similar system with about 250 clocks in the terminal proper at 33rd Street, and a separate synchronizing circuit running eastward to the Sunnyside freight yards at Long Island City and in the opposite direction as far west as Bristol, Pa., a distance of 67 miles.

Local subway lines are similarly equipped. The Interborough Rapid Transit System uses about 600 self-winding clocks synchronized from a master at its 59th Street power house. The Brooklyn & Manhattan Transit has approximately 100. The Hudson & Manhattan under-river tubes has 50 synchronized by a Christopher Street master clock. Approximately 100 miles of new subway system is now under construction, and a master clock with suitable relay and battery equipment has been installed in the 53rd Street power house and is available for inspection. No estimate can be made of the number of clocks the new subway will use but probably between 200 and 300.

I refer to these private installations only to point out the fields of application of this self-winding synchronized type of movement which is essentially the same as that used throughout the Telegraph Company's time service.

Herman Lemp: A symposium of time and time services would not be complete without mentioning the work of Mathias Hipp the pioneer in this art in Europe. Those who have traveled recently in Switzerland have undoubtedly seen the electric clocks on street corners, church towers, and hotels in the principal cities. These clocks have been in continuous service since about 1868 furnishing accurate time to a critical public, makers of Swiss watches and chronometers.

At the Centennial exposition in Philadelphia in 1876 Mr. Hipp received Gold Medals for his exhibit. His electric clocks are known all over Europe. The underlying fundamentals of the first central stations established to furnish accurate electric time are found in Mr. Hipp's conception of using feeble impulses but of some duration following each other every minute with reversed polarity, to actuate polarized receiving dials. These impulses have the advantage of never causing the receiver armature to advance more than *one step at a time*, even if a bad contact such as might be likened to a wire passing over a file, should give many impulses in lieu of one. To cause the minute hand to advance another step, the current will have first to travel *in opposite direction*, and as stated above is independent of the number of impulses in the same direction. Hence if atmospheric interference should cause the hand on one dial to advance between legitimate signals the current from the master clock would find its work already done and at the next minute the dial would be in step again.

Mr. Hipp was the first to invent the tuning fork escapement for a chronoscope, used in technical schools to measure the time a ball takes to fall—say three decimeters. He then invented the Hipp escapement, a toggle joint electric contact making device, which would, upon lowering of the amplitude of a free swinging pendulum, send an impulse through an electromagnet acting upon an armature attached to the pendulum and thereby restore its amplitude. This device was unaffected by strength of current and permitted the master clock to be kept going indefinitely as long as electric energy was supplied and with an accuracy of a few hundredths of a second variation per day.

It was my duty in 1878 to correct the master clock of the city of Neuchâtel every noon, by signals received from the Observatory of the same place. To ascertain deviation from observatory time Mr. Hipp invented the "coincidence clock," doing for time what a vernier scale does for linear dimensions. A pendulum next to the master clock pendulum had a period of oscillation of 60 beats in 59 seconds. It was released by current from the observatory and started to swing immediately. If the master clock pendulum was fast the coincidence pendulum lagged behind, each beat approaching nearer that of the master clock. As soon as the two beats coincided, the number of beats was read on the dial, indicating the number 1/60th of a second the master pendulum was fast. On either side of the master pendulum two others were provided which, when connected to the master pendulum, would either accelerate or retard the latter 1/60th for each beat they were connected. As a check the coincidence pendulum was reset again and released a second time from the observatory when, if the master pendulum had been properly corrected, the beats of the two pendulums would coincide right at the first swing.

Mr. Hipp was also the first to construct an astronomical pendulum of steel with mercury compensation (Invar was unknown at that time) located in a glass tube hermetically sealed and kept under constant (vacuum) pressure and temperature. This pendulum was located in a vault in the observatory while its dial was placed next to the observer at the transit instrument. This astronomical pendulum which had a maximum variation of 1/200th of a second per day was exhibited at the first electric exhibition in Paris in 1881 and I think another was sent to the Naval Observatory in Washington.

Mr. Hipp's successor Mr. Albert Favarger greatly simplified the polarized synchronized dials in 1905 and his book on electric time measurements is today considered authoritative.

John D. Crawford: Time (integrated frequency) and frequency (time rate) are similar aspects of the same physical idea. Yet these two ways of viewing the problems before us can cause very real differences of opinion. The discussion between Mr. Warren, who measures time, and Mr. Sporn, who measures frequency, illustrates this point.

In the field of precision measurement, on the other hand, it is significant that Messrs. Loomis and Marrison have pooled their experiences with clocks and with frequency standards, respectively, to the very great benefit of both. This paper is the first summary of the field to appear (in recent years at least) and the authors are to be congratulated. I know that I can speak for one organization interested in frequency measurements when I say that we are glad indeed to know how the other half lives.

In connection with Mr. Marrison's reference to the use of distance as a measure of frequency in terms of the velocity of light, a mention of the recently completed measurements of the velocity of light *in vacua* may be of interest. This series of experiments was undertaken by the late Dr. A. A. Michelson on a ranch near Santa Barbara, California. The measurement involved the determination of the time it took light to travel ten times between two sets of mirrors placed at the ends of an evacuated tube about a mile long. The distance, as measured by the United States Coast and Geodetic Survey, had a probable error of something like one part in three and one-half million. A crystal clock, similar in operating principle to the one described by Mr. Marrison, was used as the reference standard for time. Data that we have available on some 15 units of this type now in commercial service, indicate that, when working under the best conditions, it is capable of determining the average frequency to within three parts in ten million. The experimental details and the results of the measurements have not yet been formally published, but it seems as though the velocity of light will soon be known with a somewhat greater accuracy than heretofore.

If this increased accuracy is realized, it will be due as much to the high accuracy of comparison that is possible with a crystal clock as it is to its frequency stability. Due to the fact that the crystal is vibrating at 100,000 cycles per second, it is inherently better suited to precise, short-interval timing than is a pendulum clock whose bob vibrates once every second. Because of this greater accuracy of comparison, it is a relatively easy matter to determine with high precision the rotational frequency of the rotating mirror used in the experiment. This point has already been mentioned by Mr. Marrison.

So it may be that the Coast and Geodetic Survey will find it possible to follow out a suggestion made some time ago by Major William Bowie, Chief of its Division of Geodesy, and lay out precise base lines in archipelagoes, mountains, and other inaccessible places by means of a crystal clock and a beam of light. Distance would then be measured in terms of time and a standard base line, using the constant velocity of light as a transfer medium.

R. C. Thayer: The noon beat signals as sent out by the two telegraph companies serve a very valuable purpose to the railroads of this country. These time signals as sent on the telegraph companies' wires are picked up by the railroad companies and re-distributed throughout their own network of communication circuits, thus each of the railroad's stations, and the train dispatchers receive the correct time daily. At terminals and the more important offices clocks designated as "standard clocks" are installed, whose accuracy is checked daily and recorded, with which the trainmen can compare their watches. The ability to obtain accurate time is of prime importance to the railroads, and without which it would be impossible to operate the fast train schedules now in effect in this country.

H. E. Warren: In answer to the comments of Mr. Philip Sporn I would not minimize the difficulties that stand in the way of securing satisfactory frequency regulation. I would agree with him that the requirements today are much more severe than was the case in 1916 when master clocks as an aid to regulating frequency first became available.

At that time the need for extreme accuracy in frequency regulation was much less and the instruments which could be used were far inferior to those which are now available. Standardization of frequency was then considered of rather minor importance. Power companies were operated regularly, for what seemed sufficiently good reasons, at frequencies as much as two or three cycles above and below 60, although rated as giving 60-cycle service. Many companies which were attempting to operate at 60 cycles were actually delivering current as much as 1 cycle above or below that value on account of instrument errors.

This state of affairs was not of course conducive to extensive interconnection. The use of the master clocks by the power companies, whatever the reason may have been for adoption, did actually tend to standardize the average frequency at an exact 60-cycle value. Moreover the use of the master clocks with their very high inherent precision probably served both as a spur and an aid to the manufacturers and to the users of frequency meters. This is for the reason that errors in the meters could be very easily discovered by comparison with the master clock so that all uncertainty regarding the relative precision of different meters for use on the same system could be readily removed.

A condition has now been brought about, as pointed out by Mr. Sporn, where it is possible by commercial instruments to maintain frequency regulation that was utterly impossible fifteen years ago. Whether or not this result would have come about if the use of the master clocks as basic standards for the average value of the frequency had not been generally adopted remains at least open to question. Certainly the adoption by many power companies of methods of regulation which call for the maintenance of exact average frequency, primarily or secondarily for the purpose of giving time service to their customers, has been a rather important factor in bringing about the present situation, where practically all power companies have the same exact standard of average frequency.

I heartily agree with what Mr. Sporn has said about the extremely difficult problems of regulating station output on large interconnected systems so as to maintain tie-line loads within satisfactory limits and I certainly would not claim that the adoption of master clocks alone, has or could completely solve these problems.

One idea which I desire to convey in my paper is that the adoption of the master clocks by the power companies has, apart from the time service that has been made possible, been a factor and aid in helping to solve the operating problems of some of the very large power companies.

In answer to the comments of Mr. R. J. Wensley I would recognize the background that has been furnished by numerous inventors in this field, as in practically all fields where something worth while has suddenly been accomplished. It seems to me that in most cases, however, the merit of the work that has been done can be measured by the accomplishment.

Forces of Electric Origin in the Iron Arc

An Explanation of Overhead Welding

BY F. CREEDY[1] Member, A.I.E.E.
R. O. LERCH[2] Non-member
P. W. SEAL[3] Enrolled Student, A.I.E.E.
E. P. SORDON[3] Enrolled Student, A.I.E.E.

IT will be readily admitted that it is desirable, if possible, to reduce the study of the phenomena of high-current metal arcs, particularly iron arcs, owing to their importance in welding, to a state in which they can be exactly described and measured by a suitable number of parameters, so that the effect of any change of conditions may be specified by the changes in these parameters. Owing to its intense brilliance the arc cannot be studied directly and the most convenient way of studying it is to project the magnified image on a screen by means of a lens in the manner shown for instance in Fig. 3. When this is done a series of remarkable phenomena at once becomes apparent. Considering first a low current arc of four or five amperes between electrodes of about the same size as welding wire, say about an eighth of an inch in diameter, it is seen that the two ends of the electrodes each become fused into a globule, the positive electrode being materially hotter than the negative. In some cases the globule may be exclusively on the positive electrode while the negative electrode remains black containing only a small incandescent area corresponding to the cathode spot. On each electrode there is a brilliant incandescent spot and frequently a reflection of the cathode spot may be seen in the fused surface of the drop on the end of the positive electrode which presents a characteristic glazed appearance.

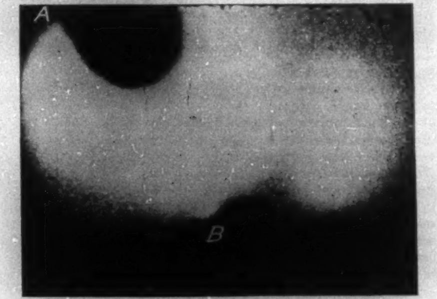

Fig. 1

The arc itself consists of a column of blue vapor surrounded by a yellow envelope of burning iron which is suppressed if the arc is struck in nitrogen or other inert gas. All this has been the subject of much study, but if an arc between electrodes of similar area but carrying a welding current of say 150 amperes is examined in the same way, entirely different phenomena become apparent. Suppose that the positive electrode is a piece of steel plate of considerable area while the negative electrode as before is a welding rod, the drop on the end of the welding rod can be seen as before but now it appears to be the seat of violent forces. It oscillates to and fro and quivers like a jelly while on its surface are to be seen what seem to be fine wave formations. Moreover it does not drop off in the same manner as in a small current of say 5 amperes when the drop leaves the electrode very much as a drop of water leaves a hose. When a powerful current is used the drop can be seen to grow to a certain diameter, usually somewhat larger than that of the rod and then there is a sharp explosion or crackling noise and the drop disappears, its motion being so fast that it is impossible to see it cross the gap between the electrodes either by the eye or by means of movie cameras of ordinary speed.

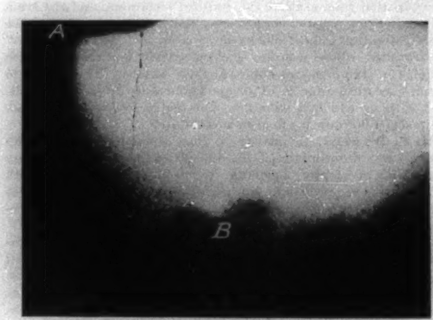

Fig. 2

In Figs. 1 and 2 are shown two succeeding pictures on a film which was given 32 exposures per second. In the first the drop can be seen clearly while in the second it has totally disappeared, (the end of the electrode being seen at *A* and the cathode spot at *B*) having therefore crossed the gap in less than this space of time (probably a great deal less). These phenomena urgently need explanation since the origin of these forces is not at all well known.

3. Senior Students 1931, Lehigh University.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

Other curious phenomena are that when welding overhead, the drop can travel in the direction opposite to that of gravity; and again, the crater or hollow space which appears to form under the welding rod requires explanation. This explanation resolves itself into two portions.

1. What is the force that causes the drop to travel across the arc space?

2. Why is it that the drop is detached with explosive violence rather than gradually? Light was thrown on the first of these questions in the following way:

1. Studying low current (five amperes) iron arcs by means of an apparatus which involved burning the arc inside a glass bell jar containing gas at atmospheric pressure it was found that, starting with a clean jar, within a few seconds of the arc being first started, a deposit began to form on the jar which gave sharp shadows of the electrode holders. This was apparently due to particles projected in straight lines which might be thought to give rise to mechanical forces on the electrodes. Within a few minutes this sharp pattern was blurred by the oxides, nitrides, etc., given off by the arc in vapor form. Investigation of these forces, whose magnitude must be far less than a gram, is difficult because the heavy arcs which it is necessary to use rapidly melt away any apparatus delicate enough to measure these small forces. Apparently the only way in which this difficulty can be overcome is to reduce the time of application of the heavy arc to a very short interval.

In order to make use of this principle the following apparatus was designed based on the principle of the ballistic galvanometer. This is shown in Fig. 3 and consists of a brass rod about 5/16-in. diameter and 8 in. long terminated at either end by an iron electrode about 3/8-in. diameter and 2 in. long. This forms the moving system which therefore consists of a double headed *T* which is suspended at the center of gravity by a bifilar suspension whose dimensions are as follows:

Length 26.6 cm. Distance apart at the bottom 2.93 cm. Distance apart at top 1.82 cm. Diameter 0076 cm. Molybdenum wire.

A galvanometer mirror is also fixed to the suspended system and reflects a spot of light on a screen in the usual manner and a pin projects from it below, dipping into a mercury cup. This forms the moving electrode. There is in addition a fixed electrode which consists of a piece of welding wire held in a clamp as shown so that it may either be brought in contact with the end of the moving electrode or moved back to any desired distance by depressing the key. The current therefore passes through the fixed electrode, the arc between it and the moving electrode, then through the moving electrode and out through the mercury cup.

To strike the arc the fixed and moving electrodes must be momentarily touched together and then drawn apart by depressing the key. This at first sight gives rise to a difficulty owing to the sensitivity of the suspension. No matter how light the contact between the fixed and moving electrode, it is sure to set the spot of light on the screen into violent oscillation which may take a long time to die away since the apparatus has no damping except that due to the pin immersed in the mercury cup. To overcome this difficulty, vanes are attached to the moving system on either side of its axis of rotation and arranged to dip into mercury troughs which could be raised or lowered by moving a lever. When the vanes are in the mercury troughs, the damping is extremely great so that contact can be made without agitating the spot of light. Having struck the arc it is possible to lower the mercury troughs and free the moving system without either shock or agitation of the spot. The method of operation of the instrument therefore consisted in striking the arc with a small current, say 5 amperes, the forces due to which are very small, then throwing on the heavy current for a short period varying from 0.1 second to 0.6 second and observing the first deflection of the spot of light. From this and the moment of inertia the impulse may be readily calculated on the familiar principles of the ballistic galvanometer. The impulse of course is defined as the force multiplied by time of application.

Fig. 3

It was also desired to study the relation between these forces and the arc length, hence the moving and fixed electrodes and the arc between them were projected on a screen as shown in the separate sketch included in Fig. 3 with a magnification of approximately 23.8 diameters which rendered the arc length readily measurable.

Examining this apparatus it is obvious that currents passing into the moving element by means of the arc and out by the mercury cup will produce certain forces in conjunction with the earth's field and the fields of other current carrying wires in the neighborhood. It is necessary therefore to find some means of estimating the magnitude of these forces. For this purpose a second electrode is provided and arranged so that an arc may be struck onto the moving electrode from below, this second electrode being vertical. This is clearly shown in Fig. 3. When an arc is struck in this position the arc forces, which the apparatus is designed to measure, will act in a vertical direction, that is in a direction in which they cannot produce any motion. Nevertheless the purely electromagnetic effects will be the same as before and hence this vertical electrode gives us a means of measuring them separately. On attempting to make these measurements, however, even with the heaviest currents, it was found that the electromagnetic effects were so small as to be quite incapable of measurement by the instrument used. By this means it was proved that the deflection obtained when the horizontal electrode was used was entirely due to the arc forces and not to these electromagnetic forces. Two different types of circuit were used to throw on the heavy arc for a short period. These are shown in Figs. 4 and 5.

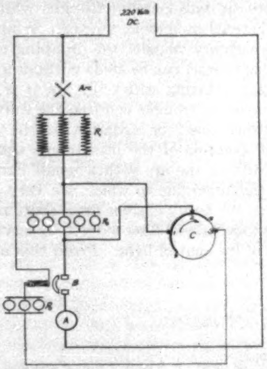

Fig. 4—Diagram of Connection No. 1

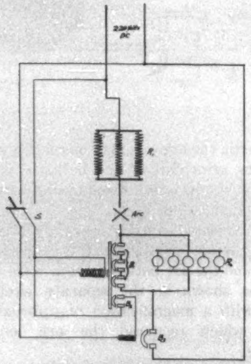

Fig. 5—Diagram of Connection No. 2

In Fig. 4 resistances R_1 and R_2 are connected in series with the arc, R_1 being of such a value as to limit the current to the value which it is desired to study, say 150 amperes while R_2 further limits it to a value of 5 amperes. A revolving contact maker C is employed which short circuits resistance R_2 between brushes 1 and 2 for a certain period depending on its speed of rotation. Between brushes 2 and 3 is connected the trip coil of a circuit breaker so that the arc circuit will be broken as soon as brushes 2 and 3 are joined. This insures that the operation of short-circuiting R_2 shall take place once only and not periodically with the rotation of the contact maker.

For very powerful currents this apparatus as constructed was not found satisfactory owing to insufficient brush area and therefore another circuit shown in Fig. 5 was employed. Here R_1 and R_2 have the same meanings as before while B_1 is a three-phase contactor, all three blades of which are placed in series, and which is fitted with an extra pair of contacts B_2 which close the trip coil circuit of the circuit breaker B_3. With this circuit the heavy arc is thrown on only for a period depending on the time lag of the circuit breaker which can be adjusted to any figure desired. This was found to give very steady and reliable results, particularly for very short time intervals.

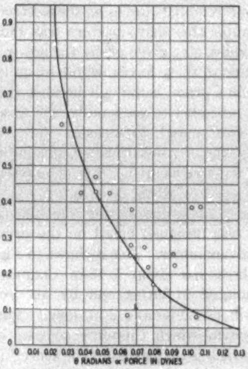

Fig. 6—Arc Length *vs.* Force ($\alpha\theta$) for 120 Amperes Inductance in Circuit Time is 0.1 Second

In using this instrument it was not found possible to regulate the arc length beforehand to the desired value before measuring the impulse. It was necessary to take a considerable number of observations with constant current and random arc lengths after which it was found that a curve could be plotted without much difficulty.

One of these curves is shown in Fig. 6 which shows the relation between the angle of deflection of the instrument in radians and the arc length. It will be seen that the points are rather widely scattered but nevertheless not so much so that a fairly satisfactory curve cannot be drawn through them. All of these instruments are rather delicate and it may be noted that the points on the curves obtained by Duffield, Burnham, and Davis referred to below are quite as widely scattered. At least one cause of these scatterings has been discovered (referred to below) and work is in progress by which it is believed it may be reduced.

A set of curves similar to Fig. 6 was observed for currents of 38, 68, 90, 120, and 154 amperes.

As may be shown easily from the theory of the ballistic instrument, the angular deflection in radians is proportional to the impulse or force multiplied by time of application. The times of application of the force corresponding to these different currents were carefully measured in the manner described below and the forces calculated from the theory of the ballistic instrument as may easily be done. (It may be noted that the moment of inertia of the moving system is 6,760 gram-(cm.)^2.) The result is shown in Fig. 7 which of course shows the smooth curves drawn through the rather widely scattered points such as those shown in Fig. 6. The most striking feature of Fig. 7 is the rapid increase of the force with decreasing arc length. Apart from this the curve for 120 amperes does not seem to be parallel to the others, at any rate for long arcs. This probably is due to the fact that arcs longer than 3 millimeters tend to take a curved form which does not lend itself to accurate measurement especially when it is remembered that this measurement has to be made within a period of 1/10 of a second.

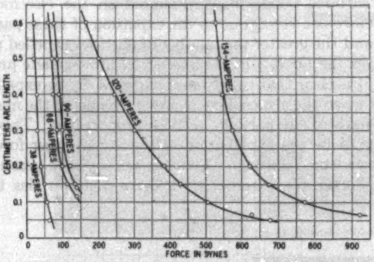

FIG. 7—ARC LENGTH *vs.* FORCE FOR VARIOUS CURRENTS BASED ON UNIT TIME

From Fig. 7 values may be taken of the force corresponding to fixed arc lengths, say 1 millimeter, and this will give 5 points for the curve of force plotted against amperes. A set of such curves is shown in Fig. 8 and it will be seen that they are approximately at least parabolas. In Fig. 9 the curves of Fig. 7 are replotted on logarithmic paper which shows that those for less than 3 millimeters are straight lines while for greater lengths some disturbing cause appears to enter which gives rise to curvature. For arcs of less than 3 millimeters therefore it is possible to obtain a simple equation. For instance for 1 millimeter $\log i = \log 17 + 0.5 \log F$ is obtained which when transposed gives

$$F = \frac{i^2}{290}.$$

For different arc lengths the constants of this equation will vary and the different values are plotted in Fig. 10 also on logarithmic paper. This gives a straight line which is parallel to other straight lines obtained by plotting arc length against force directly, these other curves being obtained simply by replotting Fig. 8 on logarithmic paper. From this curve we may ascertain how the constant in the above equation depends on the arc length and thus derive our final formula namely,

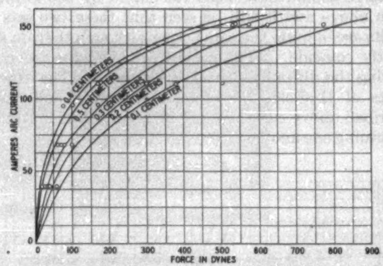

FIG. 8—CURRENT *vs.* FORCE FOR CONSTANT ARC LENGTH

$$F = \frac{0.035\, i^2}{\sqrt{l}} \quad (F \text{ in dynes, } i \text{ in amperes, } l \text{ in millimeters}).$$

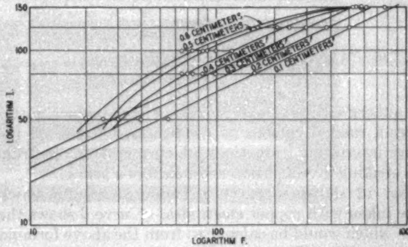

FIG. 9—LOG *I* *vs.* LOG *F* FOR CONSTANT ARC LENGTH

A study of the literature reveals that very little work indeed seems to have been done on this subject. The only papers which the writers have been able to find are a paper by Duffield, Burnham, and Davis, in the *Proceedings of the Royal Society* for 1920, v. 97, and a paper by R. Tanberg, in the *Physical Review* for 1930, v. 35.

Messrs. Duffield, Burnham, and Davis studied various materials including iron and measured the force for currents lying between 3 and 10 amperes by means of a torsion balance which must have been a very delicate experiment. The arc length corresponding to their curves is not very clearly stated but there are several references in the paper to arcs of 3 millimeters and the writers assume that this is the length of arc they employed. Their curves are reproduced in Fig. 11. Curve 1 showing the force with the moving system positive and curve 2 with it negative. Curve 3 shows what the force should have been calculated by the formula given above and it will be seen that these two sets of results are of quite the same order although they do not exactly coincide. This is hardly to be expected considering the difficulty of the experiments. The experiments of Duffield, Burnham, and Davis, and those described above can therefore be regarded as mutually confirming one another.

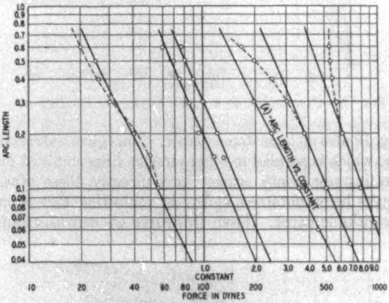

FIG. 10—(*A*) ARC LENGTH *vs.* CONSTANT, OTHER FIVE CURVES ARE ARC LENGTH *vs.* FORCE

Tanberg's results were taken *in vacuo* which introduces a radical change of conditions. A few of the many interesting deductions which may be made from this striking investigation are mentioned below.

Fig. 12 shows in curve 4 Tanberg's results which were taken with copper electrodes. Curve 6 shows the force which would be calculated from the above formula for arcs of 3 millimeters. This, of course, is for iron electrodes. But Duffield, Burnham, and Davis experimented both on copper and iron and found that the force in the case of the copper electrode is roughly double that obtained with an iron electrode under the same conditions. Curve 5 therefore has ordinates twice as great as curve 6 and might be supposed to be the curve which might be obtained by a series of experiments similar to the above, taken with copper electrodes at atmospheric pressure.

Nothing can be more striking than the difference between the forces obtained by Tanberg and those calculated in the manner just described and this difference can only be ascribed to the absence of atmospheric pressure in Tanberg's case. This therefore enables us to give a probable explanation as to why the force is so much greater with short arc lengths. The most reasonable hypothesis as to the origin of this force ascribes it to particles projected from the electrodes, particularly the cathode. The force measured on the electrodes therefore is a recoil due to the expulsion of these particles and the greater the number of particles expelled the greater the force. In the absence of atmospheric pressure it is clear that many more particles can be expelled than when the atmosphere is present reducing the mean free path of the particle to small proportions. This is likely to be the explanation of the much larger forces observed by Tanberg. Again at atmospheric pressure the shorter the external path between electrodes the greater the number of particles which can be expelled and therefore the greater the force which is in accordance with our observations.

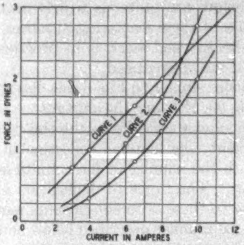

FIG. 11—CURVE SHEET NO. 1

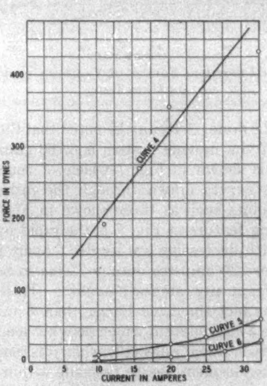

FIG. 12—CURVE SHEET NO. 2

It will be observed that the quantity measured by the instrument described above is the impulse due to the arc forces, that is the product of force multiplied by time of application. It is essential that the time of application should be accurately measured. This is normally done by measuring the speed of rotation of the revolving contact maker of Fig. 4, but in order to check this a number of oscillograms was taken some of which are reproduced in Fig. 13.

Where the circuit of Fig. 5 is employed there is no other convenient method of measuring time except by the oscillograph. Fig. 13, (No. 1) shows the current impulse when the circuit of Fig. 5 is used, the arc being excited with rotary converter current. The effect of the slots in the rotary converter on the current wave should be noted. In order to eliminate this, battery current was substituted. The result of this is shown in Fig. 13, (No. 2) from which it will be seen that the oscillations have by no means disappeared. For the reasons mentioned below, a heavy self-induction was connected in series during this test and it will be seen that instead of the current rising instantly as it does in No. 1 it rises in the well-known exponential form.

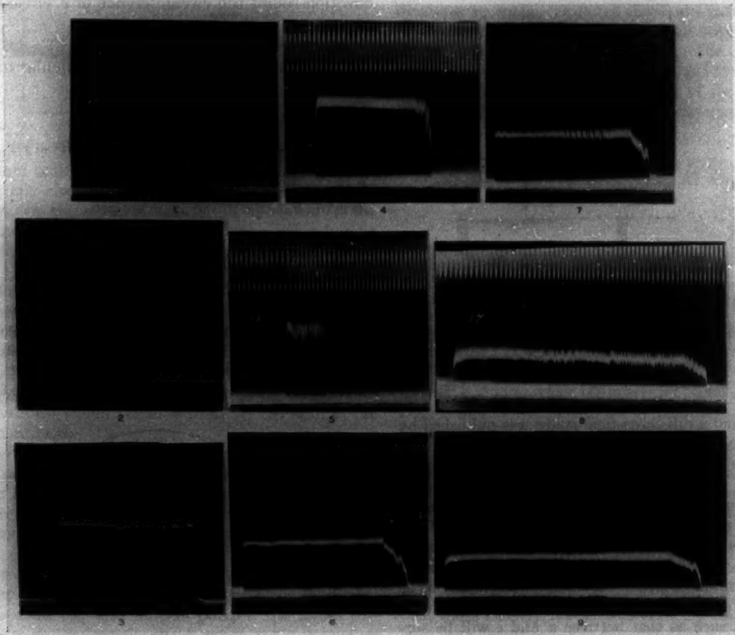

Fig. 13

When the contact maker of Fig. 4 is employed some remarkable phenomena become apparent as will be seen from numbers 3, 4, and 5. These show current impulses which correspond to the same time of closing of the contact maker. It will be seen that the times during which the current is on are entirely different in these three cases which reveal some of the reasons why the points on the curves deviate from the average. It will be seen that the current contains extremely pronounced oscillations of very high frequency. Apparently if one of these oscillations becomes large enough to reduce the current to zero, it cannot restart, so that the length of the impulse depends entirely on these oscillations, and not on the rate of rotation of the contact maker. In order to reduce these oscillations a large self-induction was placed in series with the arc circuit. The effect is shown in numbers 6 and 7 and it will be seen that the oscillations are much reduced though not entirely suppressed. Numbers 8 and 9 show a longer time period. In number 9 the oscillations are almost entirely suppressed by the self-induction but in number 8 taken under the same conditions as far as can be judged the oscillations are still pronounced.

Considering the whole series of oscillograms it will be seen that the oscillations do not start immediately the current is switched on but only after an interval which would seem to correlate them with the heating of the electrodes. This is about the only comment that can be made in general since the cause of these oscillations has not yet been discovered.

THE FORCE DETACHING THE GLOBULE

Coming to the question of the nature of the force which detaches the globule from the welding rod; about 25 years ago Carl Hering drew attention to what he called the "pinch effect" which is found in electric furnaces and a full theoretical study was published by Dr. E. F. Northrup, *Phys. Rev.*, v. 24, 1907, p. 474.

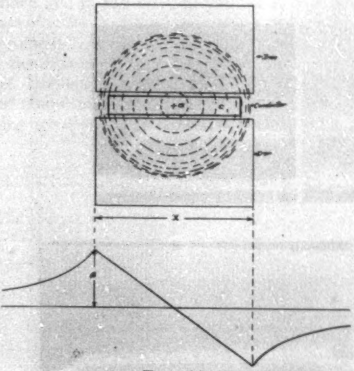

FIG. 14

In order to understand the pinch effect more clearly consider a flat conductor (Fig. 14) carrying a current of uniform current density flowing say at right angles to the paper and surrounded by magnetic material of the form shown. If we consider the central filament of current at a it will be surrounded by a field proportional to its magnitude which is very small, vanishingly so as the width of the filament decreases. A wider filament of current such as that between a and c will be surrounded by a field again proportional to its magnitude which is much greater. Hence the magnetic density will be zero in the middle of the strip and will rise in either direction towards the edges as shown in the curve below, whose ordinates represent B the magnetic density. Given this field distribution and assuming that the current is flowing upwards in the diagram, then it is clear applying the elementary rule, that the outer portions of the conductor will experience a force urging them towards the center and if the conductor is a fluid this will result in a hydrostatic pressure which becomes a maximum at the center reducing to zero at the circumference. The pressure in dynes per sq. cm. at radius r (Fig. 15) is given by the formula

$$g = \frac{I^2}{100\,\pi\,R^4}\,(R^2 - r^2)$$

for the case of a circular conductor of external radius R cm. carrying current I amperes. Clearly becoming a maximum when $r = 0$.

If the values corresponding to a welding rod 4 mm. in diameter carrying 300 amperes are inserted in the formula, $g = 7{,}000$ dynes per sq. cm. at the center of the rod. The value of g in the above formula gives us for a fluid conductor the hydrostatic pressure, which is equal in all directions. The total pressure in an axial direction round the circumference of a circle of radius r is

$$2\,\pi\,r\,g$$

and the total force on a plane perpendicular to the axis is

$$\int_0^R 2\,\pi\,r\,g\,d\,r = \int_0^R \left[\frac{2\,r\,I^2}{100\,R^4}\,(R^2 - r^2)\right] d\,r$$

Carrying out this integration we get

$$F = \text{total force} = \frac{I^2}{200}$$

The total force is therefore independent of the radius of the cylindrical conductor. If $I = 300$ amperes F = 450 dynes. This is approximately equal to the weight (at room temperature) of a spherical globule of iron 4.9 mm. (0.193 inches, a little over 3/16 in.) in diameter.

Hence for dimensions usually employed the force due to the pinch effect tending to separate the globule from the rod is at least equal to its weight particularly if it is remembered that due to the high temperature and the occluded gases the weight of the hot globule is probably a good deal less than that of the cold one.

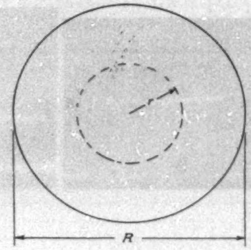

FIG. 15

Thus it is shown in general that the passage of a current through a fluid conductor, such as mercury or the molten contents of the electric furnace, causes a force of the nature of a hydrostatic pressure whose intensity is proportional to the square of the current density. Consequently if there is a constriction in the fluid path at any point so that the current density is greater there than elsewhere, the fluid will be forced out at that point and will be heaped up on either side of the constriction as shown in Fig. 16. There is then a depression in the fluid surface where the constriction occurs and a corresponding elevation at other portions, the difference of level between the two being sufficient to balance the hydrostatic pressure due to the high current density in the constricted portion. But of course a fluid cannot maintain the form shown in Fig. 16 without constant circulation hence the fluid is constantly flowing down the sides of the notch as shown in the dotted lines and being forced out of the portion having the minimum area thus setting up a circulation as shown.

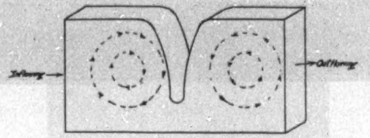

Fig. 16

It is shown above that the force starting from zero at the outer circumference of the circular conductor becomes a maximum at the center, and if a circular liquid column is arranged vertically the conducting liquid will be forced out of the center and will fall back along the outer circumference thus producing a continual fountain which remains in action as long as the current continues.

Now consider a welding rod which is arranged in a vertical position with a fluid drop on the top (see Fig. 17a) and a powerful current flowing through it leaving by an arc at the top of the fluid bead which has a diameter somewhat greater than the rod. It is not certain to what extent this bead is liquid or merely viscous. Since the diameter of the bead is larger than that of the rod, there is a constricted portion where the fluid bead joins the solid rod and at this portion the forces corresponding to the pinch effect exert their maximum power.

It was pointed out above that in the case shown in Fig. 16, the fluid in the narrowest cross section is constantly replenished by that running down the sides of the notch and that it is due to this alone that the phenomenon is a stable one, that is, that the depth of the notch has a definite value for each value of the current and may become shallower or deeper by decreasing or increasing the value of the current. But if there is a viscous fluid in which this replenishment cannot take place, then as soon as the electric forces become sufficiently powerful to overcome the viscosity of the fluid and cause the notch to begin to appear, it seems to the writers that this notch must get deeper and deeper (owing to the forcing out of the material in the smallest cross-section and to the fact that there is no means of replenishing it) until the conductor is broken in two. In other words the stability of the phenomenon depends on the free circulation of the fluid, that is on the absence of viscosity.

Now apply this to the case of the bead on the end of the welding rod. These electric forces must cause a constriction (see Fig. 17b) to form at the narrowest portion of the fluid mass, that is where it joins the solid material. This constriction forces out the material in the center of the bead the axial pressure being 7,000 dynes per sq. cm. as calculated above, and as soon as the cross section becomes smaller the pressures are increased as the square of the current density. The total force tends to sever the parts still attached, and remains constant no matter how small the area of the attached portions. Hence as soon as the constriction starts it deepens at an ever increasing rate until the bead is cut off from the rod with explosive violence in a way which can be readily observed. It may be that some of the fine wave motion which is apparently observable in the bead is due to attempts to set up a circulation such as that described in connection with Fig. 16. As soon as the globule is detached the forces measured above are ample to carry it over. For instance with a current of 300 amperes and an arc length of 0.1 millimeter the force is approximately 10,000 dynes or about 10 grams.

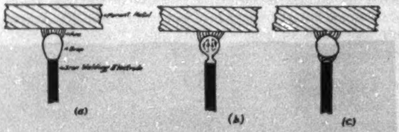

Fig. 17

Discussion

J. Slepian: Is force itself the proper measure of the capacity of the pinch effect in throwing particles from the electrode with considerable velocity? It would seem to me that impulse or work being more directly related to momentum and energy would be more appropriate units for describing the particle-throwing capacity. Hence, it should be necessary to consider either the time factor or the distance factor, that is, for how long a time can the pinch effect force act so as to give the particle momentum, or through what distance does the pinch effect force act so as to give the particle kinetic energy?

L. R. Ludwig: Mr. Creedy has attacked a rather interesting problem in his paper in attempting to describe the means by which drops are caused to travel across the arc space during welding. He has assumed that the drop first breaks contact with the welding electrode, travels across the space, and fastens itself to the work which is overhead. This, however, is not generally the case. Fig. 1, for example, is an oscillogram of the voltage and current taken during an overhead welding operation. It will be seen that the voltage drops from arc voltage to a value of about 2 volts very frequently, and it is believed that these voltage decreases correspond to a period during which the drop actually short-circuits the welding arc. In this event, it seems probable that when the drop of molten metal touches the work it freezes at the upper contact, and the surface tension will probably be sufficient to draw the drop up onto the work. It seems that Mr. Creedy has neglected to mention this possibility.

With regard to small drops, one must agree with Mr. Creedy that the vapor blast from the cathode of the arc may be an important element in the transfer of the welding material if the electrode spacing is short. If this is to serve as an explanation, however, it is essential that the welding electrode be negative and the work positive. Overhead welding is frequently done with polarities opposite to those mentioned, and this fact again seems to mean that Mr. Creedy's explanation of the transfer of material is not sufficient.

In the latter part of his paper Mr. Creedy has discussed the effect of the "pinch effect" on loosening molten drops from the welding electrode. He has calculated a force of 450 dynes, which hardly seems sufficient to explain the explosive action which he has observed when the drops leave the electrode. In order to be certain of the results, either the impulse or the momentum given to the drop should be calculated. It seems possible that the explosive action is really due to the very high temperature of the last point of contact between the drop and the electrode. The formula for the calculation of this temperature was given by Mr. Slepian before the A.I.E.E. in 1926. Thus, if it is assumed that due to the pinch effect the area common to the drop and the welding electrode is reduced to a very small value, the voltage between the welding rod and work would concentrate across the last contact point. This would give rise to a voltage drop of 2 volts across the contact (taken from Fig. 1), which according to Slepian's formula would result in a temperature of 13,000 deg. cent. at the last contact point. Although there are few data on the vapor pressure of iron at this temperature, an extrapolation would give a value of about 1,000 atmospheres. This pressure is of course exerted on a very small area, but some idea of this area may be had by calculating the amount of material vaporized as a function of the pressure, temperature, and area; finding from this and the latent heat of vaporization for iron the watts required; equating this latter result to the actual watts input and solving for the area. The result is an area of about 10^{-3} square centimeters. If the pressure given above acts on this area, the force would be about 10^6 dynes. This is much greater than the force calculated by Mr. Creedy.

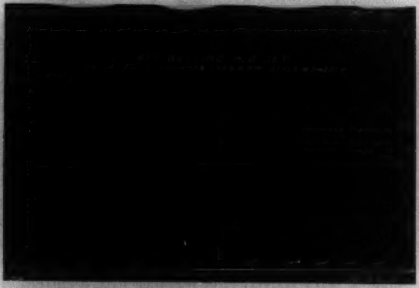

FIG. 1

Such calculations are conceded to be very rough. The calculated temperature of 13,000 deg. cent. is probably much too high, but it does seem as though the force due to this cause is of major importance in causing the transfer of welding material.

F. B. Lucas and E. C. Easton: Mr. Ludwig of the Westinghouse Company states in his discussion that the transfer of metal in arc welding is due to a globule building up on the end of the electrode until it comes into contact with the plate being welded then pinching off, leaving part of the molten metal on the plate and part on the electrode. Mr. Ludwig shows in Fig. 1 that the voltage across the arc dropped to approximately two volts at regular intervals, supposedly when metal was transferred.

FIG. 2

We have been experimenting with electric arcs and our results show that Mr. Ludwig's statements are not necessarily true in all cases.

We have constructed a contact maker which, when connected to a moving picture camera, makes electrical contact each time an exposure is made by the movie camera. This contact maker was connected in a circuit with one of the oscillograph vibrators thus recording the moving picture exposures on the oscillograph film. Using the above apparatus we have been able to see just what is happening in the arc at each instant on the oscillogram.

In Fig. 2 the moving picture film has been printed above the oscillograph film. The upper curve, No. 1, is the curve made by the contact maker. Curve 2 is the voltage across the arc, curve 3 is the current, and curve 4 is a 60-cycle timing wave. The moving pictures clearly show that a globule of metal was transferred at exposure No. 21 but there is no change in the value of voltage as shown by the voltage curve.

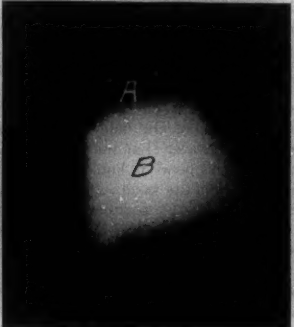

FIG. 3

Fifteen pictures such as the one shown in Fig. 2 were taken and they all gave the same characteristics.

Figs. 3, 4, and 5 are enlargements of exposures 20, 21, and 22 respectively. Fig. 3 shows the arc just before the globule passed. The globule is suspended from the upper electrode as shown at *A* and the arc is shown by the bright spot *B*.

In Fig. 4 the globule can be seen just as it starts across the arc. The globule shows up as a dark gray space at *A*. The arc in this print has become quite short.

Fig. 5 shows the arc after the globule has passed. The arc now is much longer than the arc shown in Fig. 3 due to the globule of iron passing across to the larger electrode below. It can be noticed that the arc length in Fig. 5 is just about the same as the length of the arc plus the length of the globule in Fig. 4.

These pictures show that metal can be transferred across the arc by means other than contact between the two electrodes. They also show that the transfer of metal is not necessarily accompanied by a decrease in the voltage across the arc. The voltage and current both remain approximately the same.

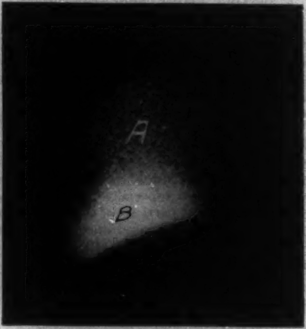

Fig. 4

G. E. Doan: So little is known about the welding arc that any data resulting from a carefully planned experiment, such as the present one, are sure to be important. For some years I have inclined toward the opinion that while the force called gravitation is the principal one in transporting arc metal in horizontal welding, that the force of first importance in overhead welding is the explosion of gases dissolved in the hot metal. If Mr. Creedy's electrodes contained gases from the beginning, I think their explosion or sudden expansion as they are heated by the arc might be responsible for at least a part of the back pressure which he has measured. These results would hold, therefore, only for electrodes of this certain gas content. The transfer by action of the "pinch effect" clearly explained by Mr. Creedy seems warranted except for one observation where it should operate but does not do so. Messrs. S. L. Hoyt and Gerald Brophy of the General Electric Laboratories observed several years ago that metal cannot be transferred upward, as in overhead welding, if the electrode is pure gas free iron, even in the hands of an expert operator. The metal merely melts and runs down the electrode somewhat as wax from a dripping candle. If the electrode contains gases, overhead welding is possible. For these reasons I consider the gas content of the electrode metal as important in determining the back pressure at the electrode and of greater moment than the pinch effect in overhead welding.

J. Leland Myer: *Pressure not necessarily due alone to particle emission from the electrodes.* The author has stated that the most reasonable hypothesis as to the origin of the force (on the electrodes) ascribes it to particles projected from the electrodes, particularly the cathode. The assumption of this same hypothesis led Tanberg[1] to the erroneous conclusion that the temperature of the cathode of a copper arc was 500,000° K. Compton[2] has shown that it is unnecessary to assign this high temperature to the cathode, as the force on the cathode can be easily accounted for by the "accommodation coefficient" of the incoming positive ions.

In addition to the original work of Duffield[3,4] referred to by the author, there is a series of interesting papers by Ratner,[5] Tyndall,[6] and Duffield,[7] wherein the exact origin of the particles and the nature of their forces are discussed. The conclusions are by no means definite. More recent work by Schmick and Seeliger[8] on the transport of material in the iron arc shows that the loss of iron at the cathode is not a linear function of time and current. This is in disagreement with the energy balance theories of Compton, Gunther-Schulze and Seeliger. It is evident that our knowledge in this general field is very meagre, and reliable data are very much needed. At any rate, it does not seem justifiable to assume that all the pressure on the electrode is caused by particle emission.

Polarity of the moving electrode not given. The author does not state whether the forces were measured on the anode or cathode of the iron arc. In view of the widely different forces measured by Beer and Tyndall[9] for the anode and cathode of a carbon arc, it would seem desirable to mention the polarity of the moving electrode in the present investigation.

Pinch effect not of sufficient magnitude to account for forces measured. The pinch effect has been applied to the arc as early as 1923 by Barlow.[10] Using Duffield's data, he found that the pinch effect accounts for less than 30 per cent of the observed force. Likewise an examination of Fig. 8 in Mr. Creedy's paper shows that the pinch effect contributes only a fraction of the forces actually measured.

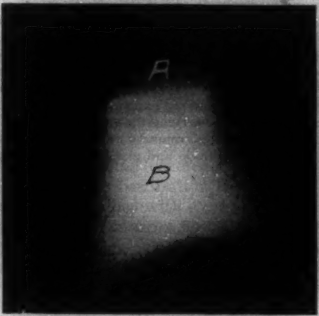

Fig. 5

For example, the pinch effect for a 100-ampere arc should exert a pressure of 50 dynes on each electrode, while the actual measurements indicate forces of 100 to 300 dynes. For 150 amperes the force of the pinch effect should be 112 dynes, while the measured forces lie between 440 and 800 dynes. The author's calculations show that the pinch effect of a 300-ampere arc gives just enough force on the average globule to counteract the action of gravity—allowing none to accelerate the globule upward. The discrepancy cited above is outstanding, and strongly suggests that there must be an additional force other than the pinch effect in overhead welding.

Gas content of the electrodes possibly an important factor. It might prove useful to know something of the quality of metal in the electrodes, particularly as concerns their gas content. The force on the electrodes might be expected to vary widely with different qualities of iron. For example, with a carbon arc, Sellerio[11] (using a torsion method also) noted that the carbon quality had a great deal more influence on the electrode repulsion forces than the arc length itself. Likewise Beer and Tyndall[9] made tests on the gas content of their carbons. On plotting time—pressure curves (maintaining constant arc length and current) they found actual pressure variations of 100:1 over a period of 12 minutes. After 12 minutes heating, the pressure reached a constant minimum value, and consistent data were then obtainable. Their final tests were carried out with degasified carbons which showed no pressure variations with time.

---

[1] See References.

If gas be present in the metal electrodes, the intense heat of the arc will certainly cause gas explosions (*i. e.*, very rapid expansion of included gas upon sudden heating). It is believed that such gas explosions afford a reasonable explanation for—

1. The unusually sudden detachment of the globule, as shown in Fig. 1 and 2.
2. The sidewise spattering of metal from the molten tip of the metal electrode.
3. The excess force which must be added to the pinch effect to account for the actual forces observed.
4. The random distribution of points on the force—arc length curve of Fig. 6, as well as on similar curves of other observers.

An obvious test suggests itself, namely the repetition of these experiments with degasified iron.

F. Creedy: The discussion shows that the paper must have been badly phrased in one respect at least since not only Mr. Slepian but Mr. Myer have fallen into a serious misapprehension as to what was meant by it. It was not intended to maintain that the "pinch effect" had anything whatever to do with the passage of the globule from the electrode to the work. According to our view the function of the pinch effect is solely to separate the globule from the electrode and if there were no other forces in existence when the globule had been so separated it would fall to the ground under the action of gravitation. Our view is that the pinch effect separates the globule which is then taken across by the forces measured in the first part of the paper, and these forces, which have nothing whatever to do with the pinch effect and which are measured but not explained in the paper, are those which are responsible for carrying the globule over.

Referring to Mr. Ludwig's remarks we agree that as soon as the connection between electrode and globule is reduced to a small area a great amount of heat would be developed which would assist the explosive effect noted, but we also think that the explosive effect is partly due to the viscosity of the molten part of the electrode. Study of the mechanics of the pinch effect, as for instance described by Dr. Northrup and referred to in the paper, will show that its stability depends on the circulation of the liquid conductor. Where no circulation is possible, the reduction of area once started must go forward with greater and greater rapidity and finally with explosive violence until the conductor is completely severed. Thus the explosiveness is explained even without resorting to high temperatures.

All those who have taken oscillograms of welding must have noted that the arc is frequently short-circuited by a globule in the manner referred to by Mr. Ludwig, but the work done in our laboratories by Mr. E. C. Easton and Mr. F. B. Lucas as mentioned by them in the present discussion, has shown that it is quite possible for the globule to pass without any indication whatever in the oscillograms. Thus not all the globules short-circuit the arc and we have to explain the passage of those that do not as well as of those that do. I am obliged to Mr. Myer for the interesting references which he has given. At the same time I can not help feeling very skeptical as to the explanation of these forces as due to the explosion of occluded gases. Since the discussion took place, tests have been made with especially purified gas free iron in vacuum and forces as high as 4 grams observed. Some of the references that Mr. Myer gives refer to work done with carbon, in some cases especially degasified. It is hardly conceivable in any case that particles of carbon in the solid form should fly off in the manner supposed since the products of combustion of carbon are gaseous. This is still more true, of course, for the degasified carbons.

An Improved A-C. Arc Welder

BY A. M. CANDY[1]

Member, A.I.E.E.

THE use of fusion welding processes has increased tremendously during the past decade having largely superseded the forge and hammer method of welding, due to the greater flexibility and continuity of the fusion processes. The two principal fusion processes are the gas (oxyacetylene) and the electric arc. This paper however will deal only with the arc process.

In lighting service both direct current and alternating current arcs have been used in the past with only detailed advantages being advanced for either because, with the electrodes used, either direct current or alternating current produces a reasonably satisfactory arc. In the welding field however the d-c. arc in the past has been used much more extensively than the a-c. arc, in spite of the fact that for a given rating the cost of the apparatus is less for an a-c. arc.

There are several reasons for this former feeling among which are:

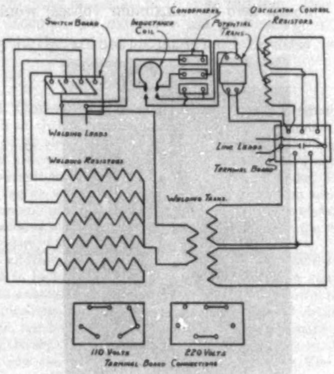

FIG. 1—100-AMPERE IMPROVED A-C. ARC WELDER

1. The open-circuit voltage of an a-c. welder is about double that of a d-c. welder thereby increasing life hazard.
2. An a-c. arc is much more difficult to strike and hold especially with bare welding wire and for vertical and overhead welding.
3. Low power factor.

The improved a-c. welder however eliminates these objections. The open-circuit (secondary) voltage is as low or lower than that of a d-c. machine. The arc is as easy to start and hold in any position under normal conditions as is a d-c. arc. In fact under certain conditions where an interfering blast (termed magnetic blow) will seriously affect the d-c. arc, the troublesome blow will be materially less when the new a-c. welder is used. The power factor at fractional loads is above that of a commercial induction motor used to drive a correspondingly rated d-c. welding generator.

The welding transformer proper shown as a part of the diagram Fig. 1 is perfectly standard in all of its design characteristics and features and is identical with standard commercial distribution transformers in construction. It is provided with a primary which can be connected in parallel or series for 220 volts or 440 volts, and with a secondary which delivers a practically constant potential of 73 volts which is used on the welding system. In this respect from the apparatus standpoint the equipment is very similar to d-c. multiple operator systems where the d-c. generator operates at a constant potential of approximately 60 volts and the current is supplied to the welding circuit through a series of control resistors for stabilizing the arc and for permitting the operator to adjust the current delivered at the arc to the value required for the work at hand. It is therefore apparent that the most interesting and novel portion of this a-c. welding equipment is that of the oscillator circuit.

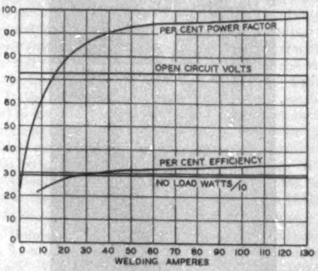

FIG. 2—PERFORMANCE CURVES OF AN IMPROVED A-C. ARC WELDER

100-ampere capacity, 110-220 volts, single phase, 50-60 cycles, 7½ kva.

Most of these and other desirable features are obtained by superimposing high-frequency oscillations on the welding circuit. The general basic idea of such use of an oscillating circuit is not new since it was

---

[1] Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

(according to records) proposed in 1879. However we do not know of any previous commercial use of the idea in this country.

The scheme of connections for the welding circuits, oscillator circuits, and power input circuit is as shown by Fig. 1. The oscillator circuit comprises a small standard transformer, a condenser across the high side or secondary, two spark gaps, and an air core choke coil. The transformer is connected on the primary side to the power input for the welder, and supplies through its secondary the necessary voltage to charge the condenser and jump the spark gaps. This produces oscillation between the condenser and choke coil of a frequency determined by the relation between the capacity of the condenser and the inductance of the choke coil. This particular equipment is designed so that the frequency is below the radio broadcast band to prevent interference and as an additional assurance a condenser is connected across the power input terminals of the equipment. On the other hand the frequency selected is sufficiently high to preclude the possibility of any injurious physiological effects upon the person using the apparatus.

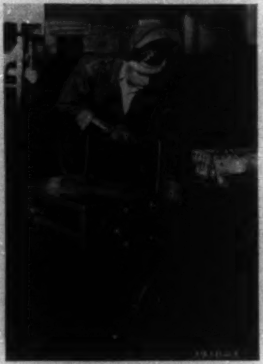

Fig. 3—Improved A-C. Arc Welder

To perform the desired functions it is necessary to have the oscillator circuit discharge between the welding electrode and the work but it is also necessary to prevent the welding circuit from supplying any energy to the oscillator, therefore two small condensers are placed in the circuit between the oscillator and the welding electrodes. These condensers block the low-frequency welding current but allow free passage of the high-frequency discharge through the welding electrode and the work. Similarly a condenser is connected across the input terminals to prevent the oscillator from feeding into the power circuit which might cause radio interference with sets in the immediate territory.

The voltage developed by the oscillator circuit is sufficiently high so that the discharge will actually start just before the electrode contacts the work. As soon as the discharge starts the ionized gases between the electrode and work produce a low resistance path for the welding current so that the arc starts very easily, in fact just as easily as a d-c. arc. Some operators actually prefer this circuit to some d-c. circuits because the arc can be started without actually making contact, thereby eliminating the sticking (freezing) of the electrode to the work.

So long as the welding arc length is maintained, the oscillator continues to discharge between the electrode and the work and eliminates the tendency for the arc to snuff out each time the welding current passes through zero. In previous designs of welding transformers these characteristics were approached by designing for an open-circuit secondary voltage of about 125 volts (compared with 73 volts for the improved transformer) and for high leakage reactance to throw the voltage and current out of phase so that when the current passed through zero the maximum voltage would be available to prevent the current from being interrupted. The old design naturally produces a very low power factor (25 to 35 per cent) compared with approximately 90 per cent for the improved transformer. (Fig. 2.)

Fig. 4—Provision for Handling

The welding operator will not experience any bothersome shock from the welding circuit nor from the oscillator circuit because of the very high frequency of the oscillator circuit producing the well-known "skin-effect," and because of the low capacity of the oscillator circuit.

The mechanical construction of the new welder is both simple and sturdy, the general appearance being as indicated by Fig. 3. The welding transformer, oscillator, and current regulating resistors are assembled in an arc-welded sheet metal case, which is provided with wheels and a suitable handle for conveniently moving the unit as shown in Fig. 4.

The current regulating resistors are connected to five switches and are designed so that currents of 4, 8, 16, 32, 64 amperes, and any combination from 4 to 120 amperes in steps of 4 amperes may be obtained. It is therefore possible to adjust the current value to within 2 amperes of any desired value. The equipment is especially desirable for welding sheet steel and aluminum in the thinner gages below No. 16 in which field the d-c. arc has not been particularly satisfactory up to the present time.

The quality of the welds made with this improved a-c. welder is in every respect equal to d-c. welds. Many tests of such welds have been made and in one series of ten tests using hot rolled steel plate the average tensile strength was 52,000 lb. per sq. inch.

Because of the low no-load losses, low investment charges and low maintenance (no rotating parts) the a-c. equipment is very economical to operate especially when welding materials of 16 gage and less. It is probably destined for extensive use particularly in fields where the d-c. arc has not made much headway.

Discussion

J. B. Gibbs: For a long time inventors and designers have recognized that an a-c. welder would be very desirable, on account of its simplicity, low cost, and absence of moving parts. Several a-c. welders have been built, but they have not found wide acceptance, for the reasons given in the paper. The low power factor might perhaps have been tolerated on account of the economy of the apparatus, but the combination of danger to the operator and difficulty of operation has made the field for a-c. welders of the old type rather small.

The addition of the oscillator removes the difficulties which seemed to be inherent in a-c. welding. It is another example of the combination of well-known ideas to produce a useful result—a combination which having been perfected is of obvious advantage, but however, requiring a breath of vision and a knowledge of the art.

The new a-c. welder is essentially a transformer. The details which are added to secure portability, current control, and stability of arc are of importance but they are so simple that the whole apparatus can be built in a factory designed exclusively for the manufacturing of transformers.

The quality of the welds made with this a-c. welder is fully up to the high standard which is expected of d-c. welds. In the series of tests mentioned in the paper, the hot rolled steel plates were welded together, machined to a standard dimension, and tested to destruction. The final failure occurred sometimes in the parent metal and sometimes in the deposited metal, indicating approximately equal strength.

The interest displayed in this welder since its announcement a few months ago indicated that it meets an existing need and that it is now feasible and economical to apply electric arc welding to many uses for which, heretofore, it has been found unsuitable.

R. E. Hellmund: During the last eight or ten years a great deal of discussion has taken place regarding the relative merits of a-c. and d-c. arc welding and the possibility of using a-c. welding to a greater extent. However, up to this time the a-c. welder has not been commercially exploited to any extent in this country. This is rather surprising in view of the fact that such welders have been commercially available in Europe for almost ten years. Quite a number of them was exhibited in England about 1924 or 1925, and on the Continent both single-phase and three-phase a-c. welding were carried on commercially about that time. Shortly after this, about 1925 or 1926, one of the first a-c. welders with high-frequency "keep alive" was commercially available in France and it gave reasonably good results as far as the weld was concerned. Unfortunately it was possible for the operator to receive severe and disagreeable shocks under certain conditions, a factor which of course would not have made this welder very popular in this country and which carried with it a certain hazard, not so much from the danger of the shock itself as from the fact that the reaction from the unexpected shock might result in other accidents, such as falling, etc.

Possibly it is to be regretted that a-c. arc welders were not available earlier in this country, as they might have hastened a more general introduction of arc welding because of their somewhat lower cost, greater portability, and the absence of a rotating member and consequent reduction in attendance and maintenance. On the other hand, if we consider that arc welding in general in the absence of reliable test methods for the finished weld had to overcome many prejudices, it may be fortunate that the inferior welds likely to be obtained with the earlier types of a-c. welders were not added to the many other difficulties which had to be overcome in the introduction of arc welding. Now that an a-c. welder which is not only equal but in some respects superior to the d-c. welder is available, it will most likely open up new fields and broaden the application of arc welding.

C. J. Holslag: As we were the first ones to manufacture a-c. welders we are naturally interested in the article presented by Mr. Candy. A description of our welders was published by the American Institute of Electrical Engineers, 1919.

The open-circuit voltage of an a-c. machine is not generally double that of a d-c. welder as stated by Mr. Candy. At the present time, the use of a "shielded" arc makes it necessary to have about 70 volts open-circuit voltage in d-c. welding. This is the open-circuit voltage of the a-c. arc welders we are now manufacturing and is the same as the a-c. welders now manufactured in Europe.

Power factor and efficiency with either alternating current or direct current are closely related. In fact, the power factor depends on how much loss there is in the welding circuit. The best conditions for welding, either alternating current or direct current, require some dead resistance. With an a-c. transformer we can weld without resistance—this results in an efficient apparatus but a poor power factor. With 75 volts open circuit and 35 volts across the arc the power factor is around 50 per cent. If resistance is introduced in the circuit, the power factor will be raised. This is also true in the d-c. circuit except that the power factor is better because of the higher loss in the motor and generator. In general, with an a-c. welding transformer we have an efficiency of 80 per cent and the power factor of 50 per cent; whereas, in the d-c. circuit the total efficiency is around 50 per cent and the power factor 80 per cent. In other words, there is about the same current demand on the main line.

Mr. Candy's second point is decidedly controversial. We would also like to have Mr. Candy comment on the safety of his circuit from the operator's standpoint especially for transformers of the larger size.

A. M. Candy: Output capacity of the welding transformer has no bearing on the safety to the operator inasmuch as the voltage of the welding circuit remains the same.

Recent Developments in Design of Arc Welding Generators

BY K. L. HANSEN[1]

Associate, A.I.E.E.

THE rapid expansion of arc welding in recent years has served in an ever increasing degree to focus attention on the design and operating characteristics of arc welding generating equipments. Up until a few years ago the d-c. arc welding circuit invariably constituted a welding system rather than a welding generator. This applies even to the variable voltage individual operator sets as well as to the constant potential multiple operator equipments. Generally speaking, the so-called arc welding generator does not possess all the characteristics required for arc welding, and to compensate for this, external auxiliary devices of one kind or another are introduced. The generator to be discussed in this paper is designed so as to have inherently all the characteristics required for arc welding without the assistance of any external auxiliary apparatus whatever, and is, therefore, in every respect an "arc welding generator."

Resistance Characteristics of Arc Welding Circuit

It is well known that the negative resistance characteristic of the arc makes it inherently unstable when operating from a constant potential circuit. To overcome this instability, the circuit must have a drooping volt-ampere characteristic; that is, the voltage must decrease with increasing current. Individual operator welding generators are, therefore, designed to have a drooping volt-ampere curve.

When there is no actual transfer of material across the arc so that its inherent resistance characteristic is the only cause for instability, the requirements are not very exacting. For example, very little more than a drooping volt-ampere characteristic is required to maintain a carbon arc. However, when there is metal transferred across the arc, as in metallic arc welding, and abrupt changes in the arc resistance are caused thereby, the conditions become much more complex and exacting.

When welding with a mild steel, bare, or lightly flux coated electrode, oscillograms show that the voltage across the arc drops to zero at more or less regular intervals. This drop of voltage takes place whenever a drop of molten metal goes across the arc and thus momentarily short-circuits the arc, at which instant the resistance of the arc is reduced to zero.

The time during which the arc remains short-circuited is exceedingly short, being on the order of one to two hundredths of a second. As compared with the length of time on short circuit, the average interval of time between drops is approximately four to five times the length of time on short circuit. The resistance of the metallic arc, therefore, varies rapidly between the value zero and such a value of resistance as to make the drop across the arc at normal welding circuit equal to the normal arc voltage.

The variations in arc resistance resulting from metal transfer across the arc are much wider and much more rapid than variations in the arc resistance caused by its inherent negative resistance characteristic. Because of the predominating character of these resistance fluctuations, the circuit to which an arc welding generator is delivering energy consists, from the standpoint of the generating equipment, of a resistance which is periodically being short-circuited at a rate of from ten to twenty times per second.

The equivalence of the metallic arc to a circuit, the resistance of which varies continuously and rapidly from a definite value to zero and back to its original value, is of great importance in the mathematical investigation of the instantaneous values of current fluctuation in welding generators. In a mathematical paper,[2] the writer made the following statement:

> It must, of course, be understood that it is not attempted to calculate the current fluctuations in the arc circuit when welding is being performed, but merely the momentary increase or decrease in current that would take place if the resistance in the main circuit is suddenly changed from one value to another; as, for example, from open circuit to short circuit. It is, however, fair to assume that any special features in design of the machine which will reduce the fluctuations when calculated in this manner will also reduce the fluctuations during the welding operation and thus help to stabilize the arc.

It has been argued against this method of treating the problem that the arc does not obey Ohm's law in so far as the voltage across the arc is not proportional to the current, but remains approximately constant over wide range of current, and that the arc should not, therefore, be considered a resistance, but an independent electromotive force. However, this objection to the method used in the writer's earlier paper does not appear to be well taken.

Regardless of whether the arc obeys Ohm's law or not, it is in its nature a resistance inasmuch as it always consumes electrical energy and voltage and is not a source of voltage. Furthermore, the reaction of the machine to abrupt and wide changes in the external resistance is, of course, precisely what it is desired to

---

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

[2] *Design of Constant Current Generator for Arc Welding,* TRANS. A.I.E.E., Vol. XXXIX, Part 2, 1920.

know. Indeed, all tests that have so far been suggested for measuring the ability of welding generators to meet properly the exacting conditions of metallic arc welding consist of methods for determining the amount and duration of the momentary increase or decrease in current when the external resistance is suddenly changed from one value to another.

TREND IN DESIGN

The importance of minimizing the momentary current fluctuations, or transients as they are frequently called, is clearly discerned in the most recent modifications made in design of arc welding generating equipments.

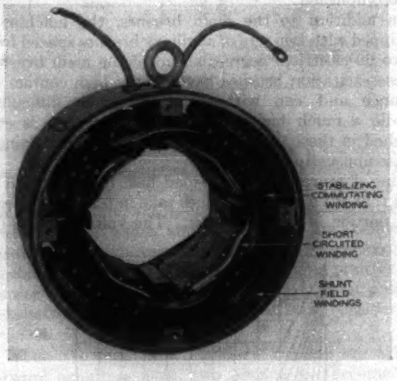

FIG. 1—COMPLETE STATOR OF 200-AMPERE HANSEN ARC WELDER

Publications which have appeared lately on the subject indicate that considerable effort has been directed toward that end. For example, in some makes of apparatus the well-known reactor, which has been used extensively to smooth out the current fluctuations, has been modified to utilize impulses from it to speed up the flux changes in the field. One such modification, known as the "flexactor," has been described by Blankenbuehler[3] and another, the "transformer reactor" by Bergman.[4] These modifications of the reactor have apparently resulted in marked improvement in operation.

In the writer's paper referred to, the desirability of eliminating the external stabilizer was strongly emphasized. Furthermore, it may be of interest to quote from this paper comments made therein on the self-excited machine in use at that time, that is, about a dozen years ago. These comments referred to the well-known system of self-excitation using a two-pole armature in a four-pole field structure and a third brush. The quotation follows:

> Since there are only two sets of main brushes, the commutator must be longer than in the four-pole machine to keep the same current density in the brushes. On the whole the material is not so economically employed as in the four-pole generator with separate excitation.
>
> Furthermore, since the series field turns generally have to be changed for different current values, either by shunting or by taps, the current adjustment is not comparable to the fine adjustment that can easily be obtained over a wide range in the separately excited machine.
>
> On the whole, the writer feels that the advantage obtained by eliminating the separate excitation is not sufficient to compensate for the disadvantages mentioned. Undoubtedly efforts will be continued in this direction, however, and if a generator can be developed possessing all the desirable features of the present separately excited machine without the need of separate excitation, the advantage of such a machine is obvious.

It probably will be conceded that an ideal welding generator is one in which:

(1) The external reactor has been eliminated, provided it has been accomplished without introducing undue complications.

(2) Current impulses in the main circuit are reflected into the field to quicken flux changes in the field and thereby make the machine more responsive to changes in the external resistance.

FIG. 2—CROSS SECTIONAL VIEW OF MAIN POLES AND SHUNT COILS OF 200-AMPERE WELDER

Stabilizing and short-circuit windings omitted

(3) The exciter has been eliminated without resorting to the two-pole armature four-pole field structure.

(4) All regulating rheostats and switches have been eliminated and still a wide range of welding currents can be obtained in fine steps which will have desirable arc characteristics over the whole range.

A generator which, in the writer's opinion, fulfils these requirements is briefly described in the following section.

COMPLETELY SELF-CONTAINED ARC WELDING GENERATOR

The first two of the objects enumerated above have been attained by a novel design of the commutating winding, shunt windings and main poles, and by adding a special winding consisting of one turn short-circuited upon itself.

---

[3] *An Improved Arc Welding Generator*, TRANS. A.I.E.E., Vol. 50, June 1931, p. 657.

[4] *A New System for D-C. Arc Welding*, TRANS. A.I.E.E., Vol. 50, June 1931, p. 678.

The armature is similar to a standard d-c. armature, except that it is wound with a relatively large number of turns and correspondingly large number of commutator bars. In arc welding generators, this is desirable for several reasons.

MMF OF STABILIZING WINDING

Fig. 3

It is generally recognized that with a high number of turns on the armature a comparatively great change in the terminal voltage requires only a small change in the field flux, which makes the machine more responsive to external resistance variations. Furthermore, with a high number of commutator bars, the volts per bar is low, which becomes a marked advantage in connection with the scheme of excitation to be described later.

Fig. 1 shows the field ring with all poles and field windings in place. It will be noticed that the commutating coils, instead of being wound in the usual way on the commutating poles, have been extended to and completely imbedded in the main pole flanges. The commutating winding thus extended and surrounded by laminations, functions both in capacity of stabilizing winding and commutating winding. The desired stabilizing effect is obtained without adding any windings to those ordinarily employed in commutating pole machines.

The method of assembling the pole flanges around the stabilizing winding can readily be observed from Fig. 1, assisted perhaps by a reference to Fig. 2. The pole, it will be noticed, is made up of two parts, the upper and the lower part or pole shoe. The upper part is bolted to the frame. The stabilizing coil, which has been wound and formed to the proper curvature on a press, is then laid in slots in the upper part of the poles. The pole shoe is then put in place and bolted to the upper part.

From Fig. 2 it will also be noticed that the generator has two shunt coils separated by a magnetic bridge. The function of this arrangement and of the short-circuited winding shown in Fig. 1 will be described later. The pole shoe, it will be seen, serves as a common magnetic path for the stabilizing flux and the flux due to armature cross-magnetization.

It may be pointed out here that the axial length of the back of the pole, that is, the part bolted to the frame, is considerably shorter than the axial length of the part of the pole constituting the magnetic circuit of the stabilizing winding.

Excitation and Current Control

The well-known reentrant volt-ampere curve of the shunt generator is not at all suited for arc welding. It is essential that the permanent short-circuit current be equal to or greater than the welding current. For that reason some source of excitation must be available even on short circuit when the voltage across the main brushes is zero. Reference to Fig. 3 will show how this is accomplished.

In addition to the main brushes, the machine is equipped with two sets of auxiliary brushes spaced from 50 to 60 electrical degrees ahead of the main brushes. These excitation brushes have a very high contact resistance and can without commutation difficulties handle a much higher voltage per bar than is ever reached in these generators, which, as already pointed out, is unusually low.

Line *A* represents the no-load field form. It will be seen that the auxiliary brushes take in part of the negative portion of the field form. The voltage across the auxiliary brushes on open circuit is therefore proportional to the rectangle *BCDE*. What will be the condition on some load, for example, on short circuit? Assume that saturation is negligible on short circuit so that fluxes are proportional to m.m.fs. The voltage on the shunt coil excited from the main brushes falls to zero on short circuit and the m.m.f. of the field is reduced to line *F*. In addition, there is direct demagnetizing force from the armature which reduces the

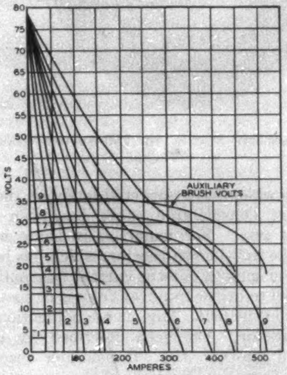

Fig. 4—Volt-Ampere Curves of 300-Ampere Hansen Arc Welder

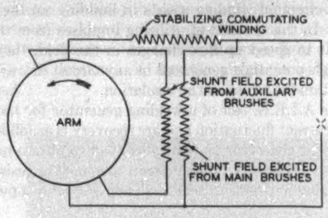
Nos. 1, 2, 3, etc., indicate different brush positions m.m.f. on the field still further to line *H*. The remaining m.m.fs. are those due to the armature cross-magnetization and the stabilizing winding.



STABILIZING COMMUTATING WINDING
ARM
SHUNT FIELD EXCITED FROM AUXILIARY BRUSHES
SHUNT FIELD EXCITED FROM MAIN BRUSHES

Fig. 5

The distribution of flux in the air gap under the main poles is not directly affected by the m.m.f. of the stabilizing winding. It is indirectly affected by this m.m.f. when the pole shoe becomes saturated, but neglecting that for the moment, the flux distribution is the resultant of the net m.m.f. of the field and the m.m.f. of armature cross-magnetization. This is shown in Fig. 3 as a dotted line. The area included between this line and the base line, and lying above the base line, represents positive flux, and similarly the area below the base line represents negative flux. It will be noticed that on short circuit there is still a considerable positive flux between the auxiliary brushes, whereas the net positive flux between the main brushes has been considerably reduced.

When the main and auxiliary brushes are shifted forward simultaneously, two phenomena become pronounced. The armature demagnetization is increased and the voltage on the auxiliary brushes is decreased. Both of these tend to reduce the current so that a wide variation in current can be obtained with a relatively small shift of the brushes. The brushes are shifted by means of a micrometer screw arrangement, making possible minute graduations of welding current.

Fig. 7—Oscillogram of 300-Ampere Welder When External Resistance is Changed from Zero to Give 25 Volts Drop at 300 Amperes

Fig. 4 shows a set of volt-ampere curves of a 300-ampere welder. It will be noticed that for larger current values the voltage on the auxiliary brushes remains about constant up to about normal current for that setting and then drops off some at short circuit. However, even at short circuit there is plenty left to maintain a sufficiently large value of short-circuit current. For lower current values, the tendency for the auxiliary brush voltage to remain substantially constant down to short circuit becomes more pronounced.

It has been mentioned that when the pole shoe which carries the flux of both the stabilizing and the armature cross-magnetization becomes saturated, the air gap distribution, and consequently the compounding of the auxiliary brushes, are affected thereby. This saturation can, therefore, be modified by introducing air gaps in the path of the stabilizing flux, as, for example, at points marked *G* in Fig. 2.

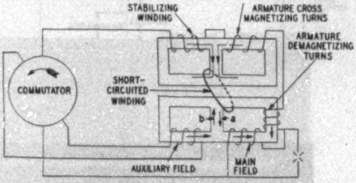


Fig. 6

Momentary Current Fluctuation and Arc Recovery

Fig. 5 is a diagram of the actual circuit of the machine, except that the one turn short-circuited winding is not shown. However, this diagram is of no assistance in forming a mental picture of the interactions between the various circuits during transient conditions, and an equivalent diagram to facilitate this has been shown in Fig. 6. It should be understood that this is not an actual diagram of the circuits, the separation of the armature cross-magnetizing and demagnetizing turns, for example, being for convenience only.

The stabilizing winding and armature cross-magnetizing turns are shown opposing each other with a common magnetic circuit, the pole shoe, between them. The armature demagnetizing turns are shown opposed to the two shunt fields and it should be observed that it is the flux within these turns which is responsible for the voltage at the main brushes. The magnetic circuit, encircled by the auxiliary field winding, is the main pole body, and the magnetic bridge is interposed between the auxiliary field and main field windings. In the absence of saturation there is no mutual induction between the stabilizing winding and the two shunt windings, so they have been shown as having separate magnetic circuits.

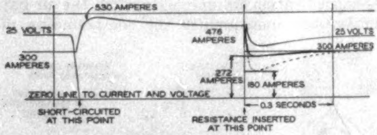

FIG. 8

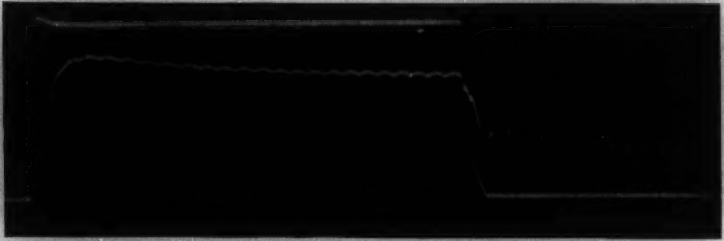

FIG. 9—OSCILLOGRAM OF CURRENT AND VOLTAGE OF 300-AMPERE WELDER IN PASSING FROM OPEN CIRCUIT TO SHORT CIRCUIT AND BACK TO OPEN CIRCUIT

The two shunt coils are excited in the same direction, and unless the main pole body is saturated, little flux passes through the magnetic bridge on open circuit. What flux there is passes through in the direction indicated by arrow *a*. On short circuit the m.m.f. of the main field winding disappears and an opposing m.m.f. of armature demagnetization appears. Now a considerable amount of flux passes across the bridge in the direction of arrow *b*; that is, instead of reducing the flux in the main pole body, which flux interlinks with the auxiliary field winding, most of it is on short circuit diverted through the bridge. The result is that the energy stored in the auxiliary field changes but very little as the terminal voltage varies up and down. The advantage of eliminating the necessity of changing the energy stored in this field when the external resistance varies is obvious.

To make the machine still faster in response to variations in the external resistance, the short-circuited winding is made to form a link between the stabilizing winding and the field windings. When the current in the stabilizing winding increases rapidly, a current will flow in the short-circuited winding, assisting in reducing the field flux. When the current in the stabilizing winding is decreasing rapidly, the transient current in the short-circuited winding assists in building up the main flux. In this method of utilizing impulses from the arc circuit to speed up flux changes in the field, there are no high potentials generated in any circuit at any time to put undue strain on the insulation.

The A.I.E.E. test of a welding generator for momentary current fluctuation and arc recovery is as follows:

Adjust generator on resistance load to obtain normal current at 25 volts. Short circuit one-half the resistance and allow current to settle. Then suddenly open the short circuit and reinsert the resistance in circuit. The current momentarily drops below normal and the time of recovery is the time required for the current to return to within 5 per cent of its original value.

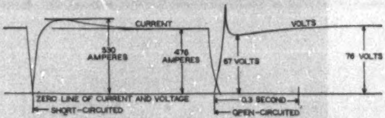

FIG. 10—OSCILLOGRAPH RECORD OF CURRENT AND VOLTAGE OF 300-AMPERE WELDER IN PASSING FROM OPEN CIRCUIT TO SHORT CIRCUIT AND BACK TO OPEN CIRCUIT

This test is of little value because the resistance variation is not wide enough to cause any noticeable depression of current below normal upon reinserting the resistance in the circuit; that is, if the machine is worth being termed an arc welding generator. The Navy specification calls for the same test for arc recovery with the exception that all of the resistance must be short-circuited and then reinserted. This test means something.

An oscillograph record of a test made according to Navy specifications at normal load on a 300-ampere welder is shown in Fig. 7. The timing is a standard 60-cycle wave. As the current and voltage scales are in opposite directions on the oscillogram, it has for convenience been replotted to scale in Fig. 8. The dotted line indicates the drop in current and the time of recovery permitted by the Navy specifications. It will be noticed that whereas the Navy permits a drop of current to 180 amperes, it actually drops to only 272 amperes.

Fig. 9 shows the record of current and voltage of the same machine in passing from open circuit to short circuit and back to open circuit. As in the preceding case, the voltage and current scales are in opposite directions, and for that reason voltage and current have been replotted to scale in Fig. 10.

Fig. 11 is a record of welding current and arc voltage when welding with a bare, mild steel electrode; average welding current, 200 amperes; average arc volts, 20.

Discussion

L. R. Ludwig: Mr. Hansen makes the point in his paper that the chief cause of the welding arc instability is the frequent short-circuiting of the arc by molten drops. Instability apparently is taken as meaning that the arc will extinguish, and must be manually restruck. The paper states in particular that when there is no transfer of material across the arc its inherent resistance characteristic is the only cause of instability and further, the carbon arc is cited as being very stable because there is no transfer of material. This stability of the carbon arc is more probably due to another reason and that is the thermionic nature of its cathode, which has been carefully discussed by K. T. Compton. The cathode of the usual welding arc is probably not thermionic as evidenced by its rapid motions.

The paper also states that variations in arc resistance resulting from metal transfer, are wider and more rapid than variations in arc resistance caused by its inherent negative resistance characteristic. It is difficult to see why the short-circuiting of the arc by drops will cause it to be unstable since the arc certainly restrikes with ease when the drop breaks away from the electrode. The only requirement placed on the generator by this bridging action is that its current must not rise to a high value during the short circuit. On the other hand the welding arc is subject to many rapid variations of voltage and current which the generator is called on to follow if the arc is to be stable.

One of the principal causes of instability may be variation in gas dissociation about the arc as suggested by Alexander in 1928. At any rate, there does not seem to be sufficient evidence just now for believing that short-circuiting of the arc by drops is the chief cause of instability.

The generator described by Mr. Hansen is a clever design which certainly combines into one machine all of the major requirements of a d-c. welding apparatus. The question of the desirability of such a combination is an economic one; the use of two associated pieces of apparatus would certainly have no disadvantage from a technical standpoint, but such design may have advantage from a standpoint of cost and simplicity.

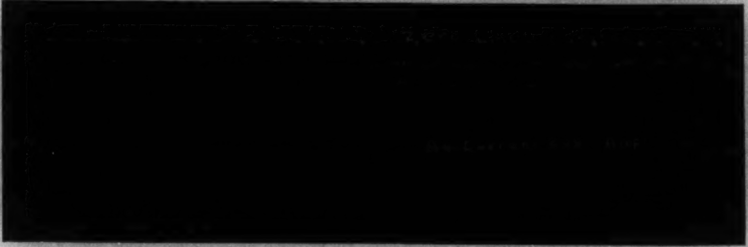

Fig. 11

The characteristic curves of Mr. Hansen's generator shown in his Fig. 4, can hardly be accepted as ideal. The stability of an arc is increased if the change in terminal voltage is made as great as possible for a given change of current. It is for this reason that an arc is more stable on a high-voltage circuit than on a low-voltage one. In order to avoid high open-circuit voltage the ideal welding generator characteristic would be quite steep in the region corresponding to about 25 volts, and flat in the vicinity of the open-circuit voltage, which is almost the opposite of the curves given by Mr. Hansen. Transient characteristic curves of course are of utmost importance, but they cannot be steeper than the so-called static curves; that is, those taken point by point.

R. E. Hellmund: Mr. Hansen has discussed in his paper an exceedingly interesting arrangement of an arc welding generator, which by skillful design can most likely be made to operate satisfactorily. I doubt, however, that the definition of an "ideal welding generator" as given at the beginning of Mr. Hansen's paper is correct for present-day manufacturing conditions. The latter dictate that in order to obtain the best economic results, all apparatus and arrangements, although they may accomplish special results, should be an assembly of standard parts manufactured in quantity. This is essential both for the sake of minimum manufacturing costs and of general availability of spare parts for nation-wide distribution at a minimum investment. While I can conceive that the solution offered by Mr. Hansen may work out satisfactorily for a small concern, it certainly is not the ideal solution for the large manufacturer. As far as the user of the apparatus is concerned, it is immaterial to him whether the desired results are obtained by a theoretical combination in a single machine or by a well-designed physical combination of standard parts; possibly he would prefer the latter in order to facilitate his renewal part problem.

Conditions as just described are often most discouraging to the engineers originating such arrangements as covered in the paper, but inasmuch as we are dealing with practical engineering questions we cannot overlook the economical factors mentioned in this connection. They are uncompromising and have prevented the commercial exploitation of many otherwise very ingenious arrangements. Of the many hundred schemes which have been proposed for combining the functions of several pieces of apparatus into one, very few have commercially survived; of those which have, the most outstanding in this country are the synchronous rotary converter, which is extremely simple, and the third-brush generator used in automobiles, which is also very simple and does not present great difficulties on account of the low voltage of the commutator and which, furthermore, is manufactured in large quantities for its own specific application. All this merely means that conditions have to be particularly favorable if specialized combination arrangements are to win out over combinations of standard parts.

D. W. Ver Planck: From a theoretical standpoint, at least, the Hansen generator is very interesting.

In all welding generators so far described it is necessary, in order to obtain the desired volt-ampere characteristic, to have a change in the amount of field flux linking the armature, as the terminal conditions vary from open circuit to short circuit or vice versa. The method of accomplishing this in separately excited machines is to cause the total flux to decrease toward zero by cancelling out the exciter m.m.f. with a m.m.f. derived from the welding current. In the self-excited machine described by Mr. Bergman* the flux from one pair of poles remains constant while that from the other set is reversed by means of a series field carrying welding current. Both of these methods require that the net number of flux linkages of the entire field circuit change by an amount equal to a little less than their no-load value. The Hansen generator is unique in that its main field flux is not changed in magnitude, but is diverted from the armature into the magnetic bridges between the coils. This involves little change in the auxiliary field linkages but the main field linkages are decreased to nearly zero. The total net change in flux linkages for both fields is somewhat less than *one-half* of the normal no-load linkages. This is an excellent point in the Hansen machine and indicates that equally as good transient characteristics as those of the Bergman type could be obtained by the use of a small corrective device.

The oscillogram of Fig. 9 when compared with the one given by Mr. Bergman seems to indicate that the two machines have about the same transient performance. However, closer examination shows that the short-circuit on the Hansen machine was interrupted quite slowly, six times more slowly than on the Bergman machine. Now it can be shown by analysis, and experience bears this out, that "instantaneous recovery voltage," or the minimum of the recovery voltage, is higher the more slowly the short circuit is interrupted. This emphasizes the need for making tests of this kind on a standardized basis so that a comparison of results will not tend to be misleading.

Referring to the volt-ampere characteristics of Fig. 4, the question arises as to whether or not the nearly perpendicular approach of the curves to the zero axis is desirable. It would seem that this is approaching dangerously near to an unstable condition.

The use of a third brush as it is done in the Hansen generator appears to be a somewhat questionable practise because this brush must commutate coils which are well under the poles where the generated voltages are high. The use of a high resistance brush may limit the short-circuit current in these coils, but even so one would suspect that considerable sparking with the consequent commutator blackening would result when the machine began to get dusty. It should be noted that the use of the excitation brush in the Bergman generator is quite different from this as it commutates coils which are in the neutral zone between the cross and main poles.

K. L. Hansen: Mr. Ludwig is undoubtedly correct in his statement that the stability of the carbon arc is conditioned by the thermionic nature of its cathode. The point which I desired to bring out was that if very wide and abrupt variations in arc resistance are superimposed on the resistance variations due to the inherent instability, the conditions, from the standpoint of the generating equipment, become much more severe and exacting than if the inherent instability alone has to be taken care of.

For example, let us assume that a carbon arc is so arranged that its negative electrode periodically touches the positive at a rate of 15 to 20 times per second, separating the electrodes to a distance of about one inch between strikes, and each time, at the moment of striking, a portion of the negative electrode is left deposited on the positive. Under these conditions, the resistance of the arc will vary between wide limits, and the conditions for thermionic emission from the cathode will change with each stroke. Also assume, as frequently happens in metallic arc welding, that there are forces present, such as magnetic fields, tending to disrupt the arc. The reestablishment of the arc after each extinction on short circuit would then probably not be so readily accomplished as Mr. Ludwig seems to think. At any rate, the demand upon the welding generator to maintain a uniform current under these conditions is without the slighest doubt much more severe than if it simply had to maintain a carbon arc with approximately constant distance between the points of the electrodes.

However, the only purpose for bringing this discussion into my paper was to justify my contention that the mathematical analysis of the arc welding generator can best be approached by investigating its reaction to wide and abrupt changes in the resistance of the external circuit. Mr. Ludwig, I believe, agrees with me on this point.

Before introducing the latest innovation, the magnetic bridge, in the Hansen arc welder, it had a volt-ampere characteristic substantially like the one described by Mr. Ludwig as being the ideal one. The introduction of the bridge, modifying the volt-ampere characteristic to the one shown in the paper, immeasurably improved the machine for welding. Whether or not the modification in the volt-ampere curve had anything to do with this improvement in operation, or whether it was entirely due to improvement in the transient conditions, such as stability and arc recovery, is problematical.

Mr. Hellmund states that the arrangement discussed in the paper "*can* most *likely* be made to operate satisfactorily." This and other statements in his discussion lead me to believe that he labors under the impression that the Hansen arc welder is just being introduced as an untried novelty. He may be interested to learn that the Hansen arc welder, in substantially its present form, has been on the market since 1927.

The number of machines now in operation is well on the way to the second thousand, one customer having had for the past three years 327 machines in operation in factory and field. Mr. Hellmund may have been influenced by the title of the paper. The more recent developments which the title has specific reference to are the short-circuited winding and the magnetic bridge, the latter being the latest innovation. However, as the distinctive features of excitation and stabilization had not been previously described in any technical publication, the machine was discussed as a whole.

It may be remarked that the introduction of the bridge has very markedly improved the welding characteristics of the generator, entirely overcoming occasional criticism in the operation of the earlier models. There is, therefore, every reason to believe that the machine will be even more favorably received in the future than it has been in the past. I wish to emphasize this because the justification for developing a distinct generator to

---

**A New System for D-C. Arc Welding*, by S. R. Bergman, A.I.E.E. Trans., June 1931, p. 678.

meet a specific application naturally depends on the number of units that eventually go into operation. When this number is large enough the machine obviously becomes a "standard" machine for that application, and the parts are regularly carried in stock.

In developing the Hansen arc welder, every effort was exerted to reduce the number of parts to a minimum. The reduction of the number of electric circuits or windings to less than one-half the number required when the usual auxiliary devices, such as stabilizer and exciter, are used, is an indication of how well that effort has succeeded. Furthermore, attention was concentrated on the elimination of those parts which experience has shown to be most vulnerable in operation.

The result has been to reduce the demand for spare parts, aside from brushes, and on rare occasions bearings, both of which are standard, to an astonishingly small amount. This was considered a much more satisfactory solution of the renewal problem from the user's standpoint than furnishing an excess number of standard parts which can readily be supplied from convenient distributing points, although the latter may have some attractive features from the manufacturer's standpoint.

As compared with another standard make of welding equipment, the elimination of unnecessary parts by correct design of the generator itself has made possible a reduction in weight from 35 to 47 per cent. Or, putting it the other way, the excess baggage required for the external auxiliary devices ranges from 54 to 90 per cent. Conservatively estimated, the average amount of finished material saved per machine is 500 pounds. The amount saved on the machines in operation so far is, therefore, moving towards the million pound mark.

If a large manufacturer, because of rigid adherence to standards, lacks flexibility to take advantage of a scheme which effects such savings while a small concern can do it, the reflection appears to be on the large manufacturer rather than on the scheme.

Mr. Hellmund is obviously under the impression that the experience of developing and assisting in putting on the market the generator in question must have been a discouraging one to the writer as the originator of the arrangements covered in the paper. I am sure that he will be pleased to know that quite the opposite has been the case. The experience has been a most interesting one and well worth while. The fact that economic forces are uncompromising is a help rather than a hindrance to those who wish to exploit new schemes of real merit. They are indeed the forces which assist the inventor in overcoming the inherent tendency in human beings to oppose change, or what might be termed human inertia. However, to succeed it is not sufficient that the proposed scheme be ingenious. It must have merit, that is, have a distinct advantage over the schemes already in use, and that advantage must in some form or other be an economic one.

Mr. Ver Planck evidently sees the full significance of the magnetic bridge between field coils, and I wish to express my appreciation of his comments on this point. The rather slow interruption of current on oscillogram, Fig. 9, at the instant of opening the short circuit, is evidently caused by the tenacity of the arc which is formed to hang on when the circuit is broken. On the earlier machines, with slower arc recovery, this phenomenon was not observed, and the voltage would have an instantaneous sharp rise due to the inductance of the circuit. Increased tenacity of the arc to hang on is obviously the result of improvement in design with reference to arc recovery. I do not believe that the minimum voltage following the first rapid rise would have been any lower if means had been employed to break the arc more rapidly. That is a point, however, which can be definitely settled by some additional tests.

Regarding the auxiliary brushes operating in the field, it was pointed out in the paper that the combination of low voltage between bars and high resistance brush has insured entirely satisfactory operation. In fact, five years of experience with this system of excitation have shown that the commutator will polish just slightly better where the auxiliary brushes are bearing on it in addition to the main brushes.

Surge-Proof Transformers

BY H. V. PUTMAN*

Member, A.I.E.E.

A short report of artificial lightning tests made on a 42,000-kva., 220-kv. shell type transformer was published in the October issue of ELECTRICAL ENGINEERING.[1] A complete report of these tests was published in the *Electric Journal.*[2] In these reports three points of particular interest in connection with these tests are mentioned: (1) the transformers tested were the largest on which lightning tests have been made; (2) the tests made were more severe than previous tests;† and (3) the transformers tested were of a new surge-proof construction involving fundamental improvements in the design of the insulation. An illustration is shown in Fig. 1 of a lightning test during which the transformer bushing was flashed over at approximately one and one-half million volts.

It is the purpose of this paper to describe the novel features of this improved transformer construction.

Two features are of special interest:

1. Without the use of shields to neutralize ground capacity, it has been possible to build shell type transformers in which the distribution of surge voltages is substantially uniform, and which are practically non-oscillating even for the longest surges.

2. A major improvement in the impulse strength of the insulation has been made through the elimination of creepage surfaces from the entire insulation structure.

Appendix I discusses the merits and limitations of uniform voltage distribution. It is pointed out that uniform distribution of voltage within transformer windings has for its object the uniform distribution of the voltage stress throughout the insulation. Even perfect distribution of the surge voltages throughout the windings equalizes the voltage stress primarily on only part of the insulation structure, which is the insulation between turns and coils. There still remain at the ends of the coil columns or groups, high stress concentrations in the major insulation between the winding and ground, which are in no way mitigated by uniform distribution within the winding. Furthermore, in shielded transformers the introduction of the large metal surfaces at line potential in close proximity to the entire high-voltage winding requires the introduction of an additional insulation structure between the shields and winding in which high stress concentrations exist. In the new surge-proof transformers the initial distribution is not only substantially uniform within the winding, but the voltage stress is fairly uniformly distributed throughout the entire insulation structure.

These results have been obtained by simply employing proper design proportions and coil arrangements—a surprisingly simple explanation of such an important achievement. A static plate has been used across the face of the first coil to assist the surge in entering the winding and to eliminate the necessity of padding the line coil. No shields have been employed.

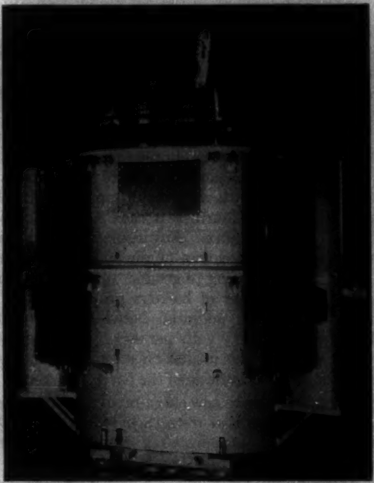

FIG. 1—LIGHTNING TEST ON 42,000-KVA., 220-KV. TRANSFORMER, SHOWING BUSHING FLASHOVER AT APPROXIMATELY 1,500,000 VOLTS AT A TIME LAG OF 2½ MICROSECONDS

Two distinct arcs are seen, because of the metal flange at the middle of the bushing

As pointed out on previous occasions, the initial distribution of surges within individual shell type groups is practically uniform because of the relatively high ratio of coil-to-coil capacity compared to the capacity to ground.[3] It is this inherent characteristic of shell type groups which has been utilized to produce an initial distribution that is substantially uniform, and to eliminate internal oscillations.

---

*Mgr. Transformer Engg. Department, Westinghouse E. & M. Co., Sharon, Pa.

†Both long and short wave surges, representative of lightning surges coming in over the line, were applied, and, in addition, a final surge having a wave front of 11,000,000 volts per microsecond was applied to simulate a direct stroke of lightning to the line close to the apparatus. This final surge was probably much more severe than any likely to be produced by real natural lightning.

[1] For references see Bibliography.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

Appendix II discusses the research work done on transformer insulation which pointed the way to the elimination of creepage surfaces.

It was reported last year by the Transformer Subcommittee that there was at least an approximate relation between the ultimate impulse strength of insulation structures as used in transformers and their low-frequency dielectric strength, and therefore the ordinary low-frequency induced voltage tests could be considered a measure of impulse strength.[4] The results of researches now indicate that this conclusion is questionable; that there is no necessary relation between impulse strength and 60-cycle strength; that the impulse ratio of a complete transformer depends on how much of the low-frequency dielectric strength is obtained by the use of creepage surfaces.

Experiments indicate that creepage surfaces have low impulse ratios compared to puncture barriers, and hence to build an insulation structure with the highest impulse ratio and therefore with the highest ultimate impulse strength requires the complete elimination of creepage surfaces.

It was found possible to apply this principle to practical designs with only very simple changes in the insulation structure. In the new surge-proof transformers the insulation barriers are arranged substantially coincident with the equipotential surfaces of the electrostatic field as explained in the appendix. Any insulation failure either between coils, or lengthwise of the coil group, or from any point in the winding to ground, must result from a puncture of a number of barriers proportional to the normal difference in potential between those points. In these transformers, "volts per inch," the design engineer's measure of the insulation strength of creepage surfaces, has become a thing of the past.

In appearance, these new surge-proof shell type transformers are not different from their predecessors. The casual observer would probably notice no difference between the core and coil structure of the old and the new. Yet the simple changes which have been made have set a new standard of performance in withstanding lightning surges.

The improvements in insulation design which have made this possible are the final achievement of several years of fundamental research. That these important results have been obtained in such simple fashion is a tribute to the skill of those engineers who participated in this development.

Appendix I

Merits and Limitations of Uniform Voltage Distribution

A fundamental problem to which consideration must be given in designing surge-proof transformers is that of reducing the dielectric stress, in the insulation, resulting from surge voltages penetrating the winding.

It is clear that nothing within the transformer winding itself can in any way affect the magnitude of surge voltages to which the high-voltage end of the winding is subjected. Whatever voltage is impressed upon the terminal of the transformer bushing is also impressed on the high-voltage end of the winding. Therefore, it is necessary to insulate between the high-voltage end of the winding and ground for the very maximum surge voltage which may be impressed on the transformer bushing by the most violent lightning surge. This voltage is, of course, limited by the flashover value of the transformer bushing, but this may be very high for surges having extremely steep wave fronts.

However, even if nothing can be done in the design to reduce the surge voltage at the high-voltage end of the winding, it is desirable to have that voltage uniformly distributed throughout the winding in order to equalize the voltage stress on the insulation between the turns and coils.* It is clear that if the surge voltage piled upon the end of the winding more insulation would be required between turns and coils at the end of the winding, and this extra insulation would be unnecessary and ineffective for normal voltage. If, however,

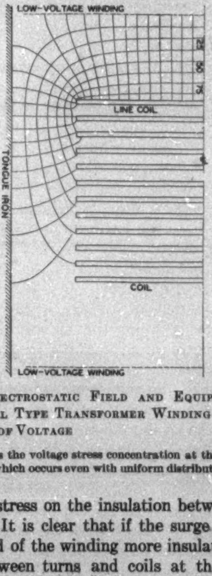

Fig. 2—Electrostatic Field and Equipotential Surfaces in Shell Type Transformer Winding with Uniform Distribution of Voltage

This plot shows the voltage stress concentration at the high-voltage end of the coil group which occurs even with uniform distribution surge voltages are uniformly distributed like the normal voltage, then the insulation which would be placed uniformly between turns and coils for the normal voltage is properly located to withstand the surge voltages also. Therefore, uniform distribution does make it possible to make the most effective use of a given amount of turn-to-turn and coil-to-coil insulation.

---

*Engineers have long recognized the merits of uniform voltage distribution and given consideration to methods of obtaining it. The condenser bushing is perhaps the best known example of an insulation structure in which means are provided to give a uniform distribution of voltage stress throughout the insulation. As early as 1912, Fortescue invented and patented (see U.S. patent 1,129,463) means of shielding core type transformers to obtain uniform distribution. The development of the cathode ray oscillograph stimulated investigations of transient phenomena in transformer windings generally, and in the case of core type transformers, led to the work of Palueff in developing means of shielding.[5]

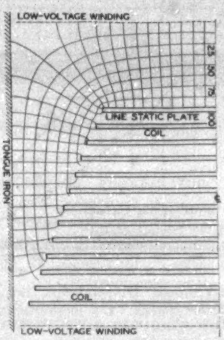

Fig. 3—Electrostatic Field and Equipotential Surfaces in Surge-Proof Shell Type Transformer Winding of the Single Group Type with Uniform Distribution of Voltage

It will be noted that the voltage stress throughout the insulation between the winding and tongue iron has been made substantially uniform and the stress concentration at the corner of the group has been materially reduced

But uniform distribution, even though perfect, does not equalize the voltage stress in any marked degree in the major insulation between the high-voltage winding and the low-voltage winding or ground. At the ends of the coil columns or groups there still remain points of high stress concentration which are practically unaffected by the distribution of voltage within the winding. In Fig. 2 is shown a plot of the electrostatic field with uniform distribution of voltage showing these points of concentration at the end of a shell type group. Similar points of concentration occur in core type transformers at the ends of the coil columns. Figs. 3 and 4 show similar plots for two of the winding arrangements used in the new surge-proof transformers. It will be noted in Figs. 3 and 4 that points of stress concentration have been greatly reduced throughout the entire insulation structure and the insulation is stressed substantially uniformly at all points. This is a very important result. Uniform distribution, desirable as it is from the standpoint of the turn and coil insulation, is only a partial solution to this major problem of equalizing the voltage stress throughout the entire insulation structure. But this major problem has been solved directly in these new surge-proof transformers and by the simple expedient of employing proper design proportions. In solving it, a distribution of surge voltages which is substantially uniform within the winding follows as a secondary result.

There is nothing in this simple method of solution which in any way limits its application to practical transformer designs. Fig. 5 shows a distribution curve plotted from test results on a sample transformer having a single shell type group. Fig. 6 shows a comparison between calculated and tested results on another sample transformer. Fig. 7 shows the same comparison for the 42,000-kva., 220-kv. transformer mentioned in the paper. Fig. 8 shows a calculated initial distribution curve for a 20,000-kva., single-phase, fully insulated transformer to be used for single-phase railway distribution.

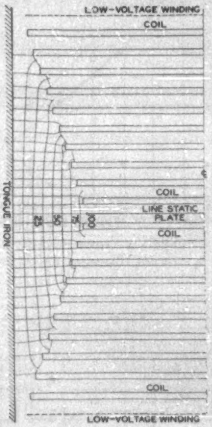

Fig. 4—Electrostatic Field and Equipotential Surfaces in Surge-Proof Shell Type Transformer Winding of the Twin Group Type with Uniform Distribution of Voltage

Since the high-voltage lead enters the middle of the group, voltage stress concentrations at the corners are inherently eliminated, and due to the construction, a uniform stress distribution throughout the entire insulation structure is obtained

No discussion of this subject would be complete without touching on the subject of internal oscillations produced by surges. Engineers are agreed on the following facts pertaining to internal oscillations:

1. Surges cannot produce severe internal oscillations unless the duration of the surges is longer than the natural period of the transformer.

2. Surges cannot produce severe internal oscillations regardless of their duration if they are uniformly distributed throughout the winding.

3. In certain types of transformers where natural periods are such that violent internal oscillations occur due to ordinary long wave lightning surges, such

oscillations may overstress and cause a failure in the major insulation between winding and ground, unless these stresses have been taken into consideration in the design of the insulation.

The shell type transformers with graded insulation previously manufactured by the company, with which the writer is connected, have not been subject to violent internal oscillations because their natural periods have been much longer than the wavelength of surges of any appreciable magnitude produced by lightning. On this account, no failure of major insulation has ever occurred in these transformers due to lightning surges. While the new transformers have much shorter natural periods than their predecessors, they are practically nonoscillating because surges are distributed substantially uniformly throughout the winding. Fig. 7 shows both the initial and maximum surge voltage distributions. In all these tests surges having a steep front and a very long tail (60 microseconds to half value) were used. Test points taken both by sphere gap measurements and by cathode ray oscillograph are shown. These indicate close agreement between calculated and tested results. As would be expected, the results show no appreciable internal oscillations.

Appendix II

Improvements in Transformer Insulation

It is well known that insulator strings, needle gaps and similar structures have a much higher dielectric strength when subjected to impulse voltages than when subjected to 60-cycle voltages. The ratio of the impulse strength to the 60-cycle strength is called the impulse ratio. For a particular structure, the impulse ratio is constant for a given wave, but for very short waves the impulse ratio increases in value. Tests on insulation samples indicate similar characteristics. The report of the Transformer Subcommittee published in 1930 states that different types of transformers having the same low-frequency dielectric strength have about the same impulse strength, and therefore about the same impulse ratio.

A very simple experiment can be performed which might cause one to question this conclusion. In Fig. 9 is shown an electrode separated from a ground plate by an insulation barrier. The whole is immersed in oil and tests made to determine the dielectric strength of the barrier as function of its extension beyond the electrode for both low-frequency voltages and impulse voltages. Fig. 10 shows the results. The low-frequency dielectric strength increases rapidly with the extension, but there is no measurable increase in the impulse strength as the extension is increased. If the impulse ratio is plotted as function of extension, it is seen that the greater the extension the lower the impulse ratio. Here at least is a humble example of a type of insulation structure whose impulse ratio may vary over a wide range.

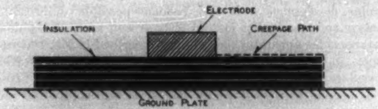

FIG. 9—EXPERIMENT TO DETERMINE CHARACTERISTICS OF CREEPAGE PATH

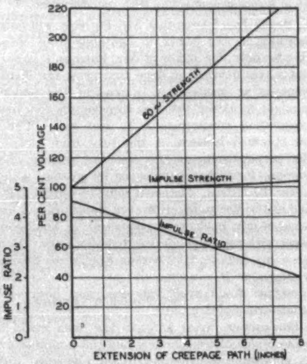

FIG. 10—DIELECTRIC STRENGTH OF A CREEPAGE SURFACE FOR 60-CYCLE AND IMPULSIVE VOLTAGES

This simple experiment seems to indicate that the creepage surface over the barrier gives practically no impulse strength. In Fig. 11 is shown the electrostatic field through the barrier of Fig. 9. The equipotential surfaces cut obliquely through the surface of the barrier. Similar creepage surfaces located in essentially the same manner with respect to the electrostatic field are found in both core or shell type transformers extending lengthwise of the coil groups or columns. See Fig. 2, Appendix I. It is also known from field experience and from tests on sample transformers that failures due to surge voltages very often take place along these surfaces.

Accordingly, an investigation was made to see what effect the elimination of these creepage surfaces from the transformer insulation might have on its impulse strength. Two sample transformers were built with the same insulation clearances. One was insulated in the conventional manner; in the other, creepage surfaces were eliminated. Both were tested to destruction with impulse voltages. The one without creepage surfaces withstood nearly twice as much voltage as the other.

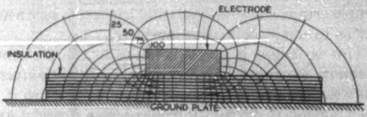

FIG. 11—ELECTROSTATIC FIELD DISTRIBUTION BETWEEN ELECTRODES OF TEST PIECE

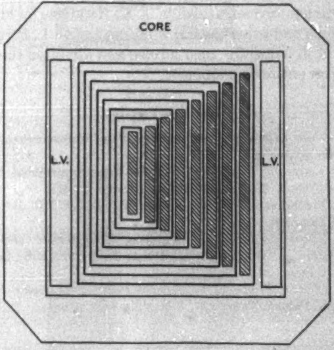

FIG. 12—ARRANGEMENT OF INSULATION BARRIERS IN THE HIGH-VOLTAGE WINDING OF THE SURGE-PROOF TRANSFORMER

These and similar investigations led to the conclusion that the impulse ratio of a complete transformer depends on how much of the low-frequency dielectric strength is obtained from the use of creepage surfaces.

It follows that for the maximum impulse ratio, creepage surfaces should be eliminated entirely from the insulation structure. This means that the insulation barriers should be coincident with the equipotential surfaces of the electrostatic field. While this cannot be accomplished exactly in a practical design, it has been very closely approximated. In fact, any failure in the insulation structure from one coil to another coil or to ground must result in the puncture of a number of barriers proportional to the normal potential difference between those points.

Fig. 12 shows how this is accomplished by the unique arrangement of the insulation barriers between coils and the core. By referring to Fig. 3, which shows the electrostatic field, it will be seen that the surfaces of the barriers lie essentially along the equipotential surfaces.

It will be noted that the same proportions and arrangements of coils which have made it possible to equalize the dielectric stress so well throughout the entire insulation structure have also made possible this simple arrangement of insulation barriers in such a manner as to eliminate creepage surfaces.

This is indeed a simple solution to the problem of building surge-proof transformers. Its effectiveness has been proved by the most drastic tests which it has been possible to devise. It resulted from a careful study of the basic fundamentals of the problem.

In conclusion, the writer desires to acknowledge the helpful assistance of P. L. Bellaschi for his invaluable theoretical investigations, of J. K. Hodnette for his suggestions and experimental work, and of C. L. Fortescue and F. J. Vogel for their advice and direction throughout this entire development.

Discussion

R. E. Hellmund: While in Europe in the summer of 1925, I was very much surprised to find that it was quite general practise with most manufacturing concerns on the Continent to carry out both experimental and commercial surge tests on insulators and transformers. Apparently such practise had been initiated shortly after the war, and by 1925 had been quite generally adopted. Since this was in marked contrast to American practise at that time, I was naturally interested in learning why such a difference existed. Although it was of course impossible to obtain very definite reasons, answers to my inquiries gave me the impression that the practise of surge testing in Europe had been brought about by a greater number of failures of transformers in service, which in turn most likely should be considered as an aftermath of the war in so far as it had undoubtedly interfered with normal design progress. In other words, the European engineers evidently were forced to the expediency of surge testing at a time when, due to the lack of sufficient data on surges occurring in service and the lack of means for analyzing their laboratory and commercial test data, the entire procedure contained a great many elements of uncertainty. Nevertheless, this may have contributed to the improvement of their designs, which seems to be somewhat borne out by the fact that they have now obtained a great degree of reliability in service.

In contrast to this condition prevailing in Europe, the service record of high-voltage transformers in America always had been very satisfactory and it was therefore quite natural that the American engineers should have hesitated to introduce the practise of surge testing until sufficient data had been accumulated with regard to surges actually occurring in the various systems and until, by the use of the cathode-ray oscillograph and similar developments, it had become possible definitely to analyze and standardize factory tests as well as to study design features of the apparatus such as those described in Mr. Putman's paper. In the absence of definite operating troubles, such orderly procedure was undoubtedly justified until now, when after a great amount of work has been carried on and completed along this line, surge testing not only can be carried on but also can be interpreted as a measure of what might be expected of a piece of apparatus in actual service. The practise now arrived at in this country is, as a result of the more deliberate method of developing it, in marked contrast to the European methods previously mentioned. In nearly all cases, the latter consisted of the discharge of the stored energy in the transformer winding itself, usually at relatively low voltages, while, with the testing methods referred to in Mr. Putman's paper, a surge involving several times the rated voltage, considerable amounts of energy, and very steep wave fronts is impressed upon the transformer winding from a surge generator and recorded by means of the cathode-ray oscillograph. Although the method of testing with surge generators was used in Europe in 1925 in connection with lightning arresters, insulators, and switches, I did not find any instances of its use in connection with transformers.

F. W. Peek, Jr.: I hope that Mr. Putman will continue the research which he has begun on lightning-proof transformers. I will discuss only one phase of Mr. Putman's paper. Fig. 9 illustrates a test devised to show that creepage distance is of little value as an insulation. In reading the paper the impression might be gained that this corresponds to a usual transformer insulation arrangement. It does not. The poor results are obtained because of the very high stress between electrodes perpendicular to the creepage surface. This stress starts corona, for either impulse or 60 cycles, which causes leakage over the surface. The effect could be temporarily stopped by boxing in the electrodes. However, deterioration and failure would soon result. Such an arrangement is analogous to the transformer with very high stresses between coils. Such dangerous stresses are indicated by corona discharges during the induced voltage test if measures are taken to detect them. The skilled designer would avoid this condition because it would mean a transformer of short life.

C. L. Fortescue: Great progress has been made in recent years in the design of transformers and the manufacturers have made an important contribution to the electrical industry in bringing out these surge-proof non-oscillating transformers. The principles used in obtaining these results have been known for a good many years, perhaps the first germ of the idea was incorporated in a transformer constructed at Cornell in 1899 by Professor Harris J. Ryan with the aid of Mr. E. F. Scattergood using what he has called the "sectored guard surface." About 1908 Mr. Reynders conceived the idea of using alternate layers of insulation material and conductors in transformers but, while he had all the elements for obtaining the surge-proof transformer, he failed to coordinate the field distribution of the coils with that of the insulating structure. In March 1913 in a paper before the A.I.E.E., I showed that it was possible to group a system of conductors of different potentials so that they will assist in insulating one another. In the discussion there was a great deal said about the principles of shielding insulating structures, illustrated by the theory of the condenser terminal and methods for obtaining uniform distribution of voltage over insulator assemblies, and so forth. The discussions illustrated rather forcibly the confusion of mind that existed at that time with regard to surges in general, surges being often referred to as high-frequency voltage and sometimes as high-frequency surges and this confusion of mind still exists at the present time as illustrated by the many requests by engineers as to the frequency of the lightning surge and references to artificial surges as having a certain frequency. In the discussion I pointed out that transformers designed on the electrostatic principle expounded in this paper could be made highly resistant to surges. In applying this principle to produce non-resonant transformers the so-called condenser type insulation could be used to insulate the core and case from the windings. In this way the winding space is isolated from the external space and through condenser action between the high-and low-voltage cylinders and plates produces a uniform electric field in the winding space which will therefore have the same potential distribution as the windings themselves as determined by electromagnetic induction. The use of condenser action to obtain desirable field distribution in isolated space is plainly stated in the paper and discussion, and in the text of my patent No. 1,129,463 and reissued patent No. 14,473. The essential requirement to obtain strength against impulses is that the dielectric circuit shall conform at every point with the electromagnetic circuit. This is the principle on which the present surge-proof transformers are based.

In 1915 Weed presented before the A.I.E.E. a paper on surges in transformers and in 1922 he was the author of a paper describing surge-resistant winding structures. More recently important contributions were made by Blume, Boyajian, Palueff, Hodnette, Bellaschi, and others which were directed towards simplifying the structures. Unfortunately there was not much incentive to designing transformers to withstand a lightning surge, the reason, I think, being that lightning was regarded as an act of God and it was assumed that nothing much could be done about it. It was realized that in most cases the lightning stroke was too far away to cause much damage and it was assumed that if it struck the line it was all up and nothing could be done about it. However, various protective devices were used and engineers were satisfied that nothing more could be done to insure the transformer windings against lightning.

The lightning failure at Wallenpaupack had the effect of rousing transformer designers from their false feeling of security and while I feel that danger to transformers has been somewhat exaggerated in some quarters, the jolt was just the stimulant required to start designers thinking about the importance of the dielectric design of transformers. I have always emphasized the importance of the dielectric circuit in transformers but exigencies of manufacture and the lack of knowledge of lightning surges acted as a deterrent in development progress. However, the work of recent years must be highly commended for the reason that the dielectric problem under surge conditions has been solved by recourse to relatively simple expedients which produce transformers presenting no serious difficulties in manufacture. In general, the simpler the insulating structure the better it is from a manufacturing and operating standpoint and in this respect the surge-proof shell type transformer must be acknowledged by everyone to be ideal.

A. B. Hendricks, Jr: The construction described appears to be logical and successful, and good results have been obtained under test.

Of "the three points of particular interest" mentioned, the third states; "transformers tested were of a new surge-proof construction involving fundamental improvements in the design of the insulation."

These "fundamental improvements" are not so very new. Fig. 1 is from my own drawing of a transformer which I designed and built and put in service in 1906, which exemplifies the fundamental principles involved. The winding is of the concentric form with circular coils, but the insulation is varied more or less in proportion with the voltages, and by the use of interleaved cylinders, flanged rings and formed insulating casing presents an absolute barrier between the high-voltage winding, low-voltage winding and core. I well remember my own statement at the time this transformer was built, that the insulation formed "an absolute and complete barrier and little or no dependence was placed on mere surface distance."

Since the middle point of the high-voltage winding is connected to the core, the voltmeter coil is located at the same point.

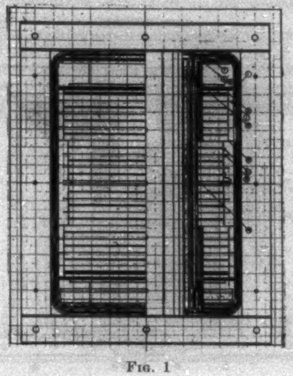

Fig. 1

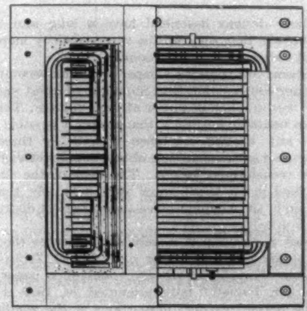

Fig. 2

The two coils at each end of the series are strip-wound, one turn per layer, the insulation between turns and coils being greatly reinforced. These were called "buffer coils," and I think this was the first design to which this term was applied, and it has persisted ever since.

Fig. 2 shows a 300,000-volt transformer of similar design built in 1913, the insulation in this case being in three steps.

Fig. 3 shows a 500-kilowatt, 578,000-volt transformer, being one unit of our original three-phase million volt outfit, as described in the A.I.E.E. JOURNAL October and November 1922. In this design, the insulation of the coil groups is varied in many steps, each group being also heavily taped separately and insulated from the adjoining group by collars. A heavily insulated large radius static plate is placed at the top of the coil stack.

All of these three designs are testing transformers with concentric windings, in which the boxing covers three sides only of the coil group, the fourth side being insulated by the taping and collars.

The principle is identical with the scheme described in Mr. Putman's paper, in that the barriers are placed along the equipotential surfaces. Such an arrangement is common practise in transformer design. Naturally, our later designs show an improvement in arrangement of the insulation over the earlier ones.

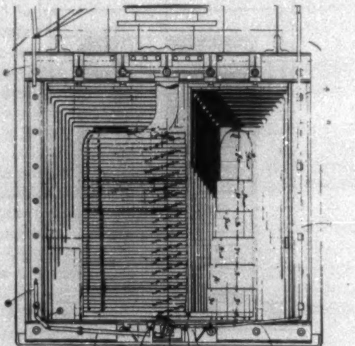

Fig. 3

While these designs described have a long and honorable history, I believe that they will be superseded by more modern and efficient designs of the non-resonating type.

J. F. Peters: Mr. Putman's paper covers an accomplishment in transformer construction that should be of great value in the economical transmission of power at high voltage. This type of construction contains flexibility that makes it possible to obtain practically any desired reactance in two- or three-winding transformers and at the same time obtain impulse strengths never obtained in transformers before. The tests of the 42,000-kva. units described in his paper show very definitely that proper proportioning of the windings gives almost perfect distribution of all impulse voltages.

This is not a surprise; it merely demonstrates theory. In a discussion of Mr. Palueff's paper on *Effect of Transient Voltages on Power Transformer Design*,* and of a paper by Mr. Brand and Mr. Palueff,* both presented in 1929. I pointed out that the proper physical proportions of the windings have a great deal to do with getting a good distribution of impulse voltage along the coil group and in keeping the amplitude of oscillations between the initial and the final distribution relatively small.

Mr. Putman's paper proves the correctness of those statements both as to voltage distribution and practical elimination of internal oscillations. In addition, he shows how to obtain impulse strengths of extraordinary value.

J. E. Clem: Near the end of the first page of this paper there is a statement to the effect that the "initial distribution of surges within individual shell type groups is practically uniform" and that this is an "inherent characteristic of shell type groups." It is rather difficult for me to visualize the basis of these statements since my transformer experience and understanding of transients in transformers would lead me to draw an entirely different conclusion. In support of my belief that the initial distribution in a non-shielded shell type transformer is not uniform, I refer to Mr. Palueff's discussion of J. K. Hodnette's paper, A.I.E.E. Trans., Vol. 49, 1930, No. 1, p. 75, Figs. 4 and 5.

Reference to the coil sketch in Fig. 5 of the above discussion shows that the inside turn of the first coil was connected to the inside turn of the second coil and the outside turn of the second coil to the outside turn of the third coil (adjacent connection) and so on down the stack. It has been claimed that the difference between the voltages along the inside of the coil stock and those along the outside of the coil stack could be removed by changing the connections so that the inside of coil No. 1 was connected to the outside of coil No. 2 (cross connection) and so on down the stack. Although some shell type transformers may have been built in the past with this type of connection, I believe that the practise has been abandoned on account of the hazard. That a hazard will be introduced by this type of connection is substantiated by the following quotation from a discussion by Mr. J. F. Peters, which appears on page 701 of the 1929 Transactions, "but it is then necessary to carry the series connections through the oil ducts between coils where the space is necessarily limited and, therefore, produce somewhat of a hazard."

The initial distribution in a shell type transformer is not uniform even though the coils are cross connected. This is made clear by reference to Fig. 4, which shows the initial distribution over a group of shell type coils connected first one way and then the other. The solid curve shows initial distribution when the coils are adjacent connected. The dotted curve shows the initial distribution when the coils are cross connected. The sawtooth appearance so pronounced when the coils are adjacent connected is not entirely eliminated by the use of the cross connection. The low points when the coils are cross connected occur at a point along the face of the coil nearer the inside than the outside end. Actually, the voltage between the first pair of coils along the outside is higher when the coils are cross connected than when they are connected in the other manner, the figures being 60 per cent and 51 per cent of the applied voltage respectively. It is very apparent from these curves that the initial distribution of a non-shielded shell type transformer can not

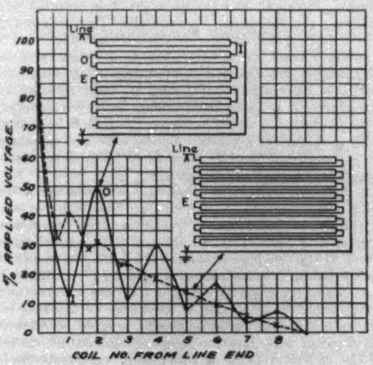

Fig. 4—Initial Voltage Distribution Non-Shielded Shell Type Coils (Clem)

be made uniform by using the cross connection method of connecting the coils.

---

*A.I.E.E. Trans., 1929, Vol. 48, Part 3.

The author claims that a short stack of wide shell type coils inherently has a better initial distribution than a long stack of narrow (core type) coils. Comparison of Fig. 5 and the solid curve of Fig. 4 of this discussion indicates otherwise. The coil stack in Fig. 5 was obtained from the coil stack in Fig. 4 by making the coils narrower and the stack correspondingly longer, the same values of winding being used, however, without changing the insulation. Non-modification of the insulation makes the comparison more favorable for the shell type group, since the wider coils would of necessity have a higher voltage between them and thus require more insulation. Comparison of the curve in Fig. 5 with the solid curve in Fig. 4 shows that the distribution for the shell type winding is actually less uniform than that for the equivalent core type winding. It follows, naturally, that the initial distribution in a non-shielded shell type transformer is not inherently uniform.

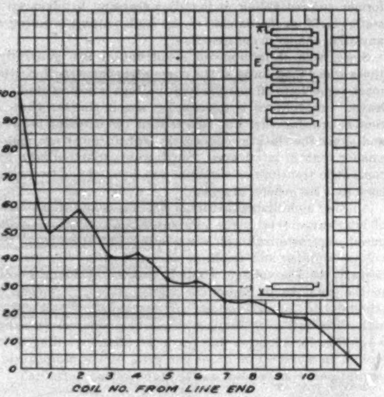

FIG. 5—INITIAL VOLTAGE DISTRIBUTION NON-SHIELDED CORE TYPE COILS (CLEM)

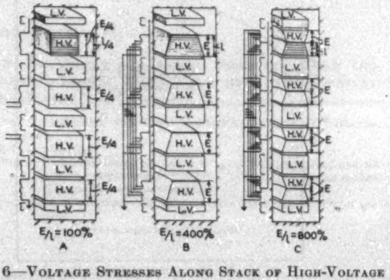

FIG. 6—VOLTAGE STRESSES ALONG STACK OF HIGH-VOLTAGE WINDINGS UNDER ASSUMPTION OF UNIFORM VOLTAGE DISTRIBUTION

A. Conventional design of shell type transformer. (Total voltage is distributed between all groups)

B. New shell type design (full voltage is applied across each group)

C. New shell type design, twin groups. (Full voltage is applied across each half of each group. Maximum voltage per unit length of stack, maximum number of interconnections and leads)

K. K. Paluef: The outstanding features of the core-type transformer as ordinarily built for grounded neutral service, are: first, the winding consists of two multiple paths from the middle of the stack to the ends (see Fig. 4 of Putman's paper); second, the winding is made non-resonating by means of an electrostatic shield connected to the line end and properly spaced from the high-voltage winding.

The first feature was adopted by us for high-voltage transformers about 1919. It eliminates the concentration of dielectric field at the end of the stack shown on Figs. 2 and 3 of the paper and therefore stresses more uniformly the insulation between high- and low-voltage windings.

The second feature was put into practise in 1926. It permits the most effective use of insulation throughout the winding since it allows accurate predetermination of voltage distribution throughout the entire structure. It also reduces the transient voltage stresses very materially by distributing them uniformly and preventing oscillation.

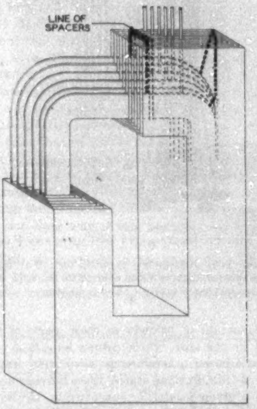

FIG. 7—CREEPAGE PATH IS SHOWN BY HEAVY DOTTED LINES

It is most gratifying to find that these essential features of transformer design gradually are receiving more general recognition, as unqualified support given to them by Mr. Putman indicates.

The practical importance attached by Mr. Putman to these two features is evident from his willingness to adopt a distribution of windings radically different from that previously employed in shell type transformers in spite of the fact that this change resulted in as much as eightfold increase in voltage stress between coils and along the high-voltage stack, and also in an increase in the number of high-voltage leads (line and taps) in the same ratio as can be seen from comparison of sketch *A* and *C* of Fig. 6 of this discussion.

Mr. Putman believes that he succeeded in the introduction of a third major improvement in transformer design "through the elimination of creepage surface from the entire insulation structure."

It is obvious from Fig. 7 of this discussion that creepage path in the new design exists on the top and bottom of the insulation in essentially the same manner as it existed in the old design. It seems to me that such a creepage path is unavoidable because if the windings were "boxed in" on the top and bottom in the manner shown in Fig. 12 of the paper, no oil could possibly circulate between the windings and tank which is an impossible condition for a power transformer.

The comparison of arrangement of windings and of the points of application of voltage in the old and new shell type design (Fig. 6 of this discussion) indicates that the full line-to-ground voltage is crowded in the new design into from 1/3 to 1/8 of the space used for it in the old design. This results in a correspondingly increased voltage between coils and density of dielectric field.

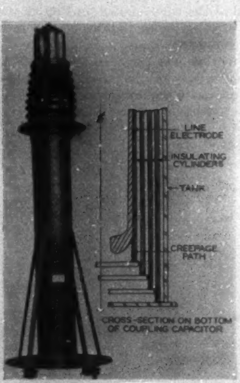

Fig. 8—Reliability of Creepage Path

Oil insulated (0.001 μf.) coupling capacitor for 110-kv. transmission system, tested in 1925 with 225 impulses of artificial lightning with amplitudes of applied waves just below or above bushing arcover

The introduction of barriers in those parts of the structure surrounded by the core, where proper length of creepage path can not be secured, therefore is absolutely imperative. Unfortunately, as Mr. Putman states, these barriers only double the strength of a given insulating space while, as shown here, the stress is increased as many times as there are groups (from two to eight times or so).

In view of all this, the stress along the creepage surfaces at top and bottom in the new design is necessarily appreciably greater than in the old. Since the vertical extension of the insulating barriers in the old design could be made just as long as in the new, it is not clear why the author expressed such a definite preference for the new arrangement of the windings.

Dielectric Strength of Creepage Path. The dielectric strength of a creepage path (whether for 60 cycles or impulse voltage) follows very definite laws, which are well known; where creepage path is used in accordance with these laws it is perfectly dependable.

One of the fundamental principles of design, where creepage path is used, is the proper proportioning of the thickness of barriers or other solid insulation to the length of the creepage path.

Another important characteristic of creepage path is illustrated in Fig. 9. It shows that the arcover voltage for a given creepage distance falls rapidly with decrease in distance between coils (or other electrodes).

This happens because the strength of a creepage path falls suddenly as soon as oil corona is formed on the edges of the coils. On the other hand, the voltage necessary to start corona is the lower the smaller the distance *d*.

Impulse Ratio. It is stated in the paper that the impulse ratio of creepage path is not a constant value, but depends on the length of the creepage path. I fail to see the practical significance of such a statement. The insulation allowances used between turns, between coils and between winding and ground, are selected by the designer without any reference to impulse ratio, but in accordance with the impulse strength determined by test for these various elements.

Non-Resonating Windings. To make a concentric type transformer non-resonating, it is only necessary to place an electrostatic shield on the outside of the high-voltage winding without any other change in construction.

Since coils of interleaved construction are generally many times wider than those of the concentric construction (they may reach some 25 to 30 in.) the high-voltage winding stack in interleaved transformers is necessarily much shorter than in concentric transformers. For this reason the stresses between coils and along the stack in concentric transformers are many times smaller than in interleaved transformers, particularly when the concentric transformer windings are located on two legs of the core, as is the general practise.

Another undesirable feature of the non-resonating transformer of interleaved type is the extremely high lightning voltage induced electrostatically in low-voltage windings from the high-voltage winding and shield as shown in Fig. 10. This happens because the low-voltage winding instead of being placed next to the core, as in concentric transformers, is placed in close proximity to the high-voltage coil and shield. From the approximate distribution of electrostatic field produced by a lightning wave, Fig. 10, it follows that the low-voltage winding rises above ground to some 60 or more per cent of the amplitude of the lightning wave impressed on the high-voltage terminal.

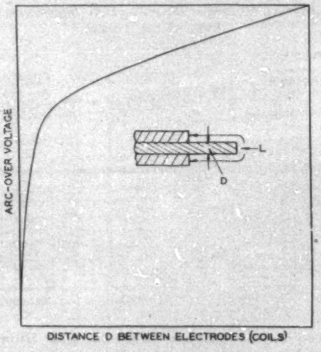

Fig. 9—Reduction of Arcover Voltage of a Creepage Path

With reduction of distance *D* between electrodes when total length *L* of path is kept constant

Incidentally, it is interesting that a single shield placed on the top of the line coil as shown in Fig. 10 can not produce a uniform voltage distribution throughout the winding. This follows from the consideration of the electrostatic field shown, which results from the fact that only a few turns of the high-voltage winding, in the immediate vicinity of the grounded end of the winding, remain practically at the ground potential after the impact of lightning wave, while the rest of the ground coil, as well as all other coils, "float" in the electrostatic field as shown.

Short Stack of Wide Coils. Calculations and tests of electrostatic (or initial) distribution of voltage produced by steep wave front are so simple that there should be no difference of opinion on the subject. In spite of it, the difference evidently exists.

For a number of years I have maintained that without a shield, initial distribution can not be made uniform or even made to approach uniformity by varying the proportions of the width of coils to the length of the winding stack. Furthermore, I know that in a short stack of wide coils without shielding, the initial distribution is extremely non-uniform. This knowledge is based on numerous tests and calculations, some of which were published by me before. Fig. 13 shows the initial distribution in an absurdly short stack of only four wide coils.

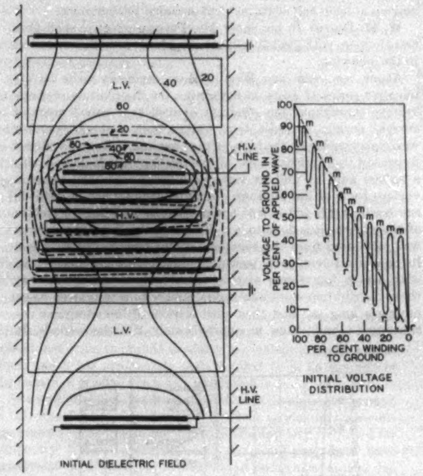

Fig. 10—Character of Initial Dielectric Field and Corresponding Initial Voltage Distribution Produced by Lightning Waves

Interleaved construction with high-voltage winding arranged similar to Fig. 3 of the paper

Solid lines—actual field

Dotted lines—Field necessary to make winding non-resonating and to prevent electrostatic induction of abnormally high potentials in low-voltage windings

l and *r* indicate the left and right edges respectively of the coils

m indicates the middle of the coils

I also previously explained that the increase in the width of the coils which gives, as stated in the paper, "a relatively high coil-to-coil capacity compared to the capacity to ground" can not have the beneficial effect, expected by some, on the initial distribution or on the subsequent oscillations.

It follows that an ordinary winding, not equipped with a shield, can not be made non-resonating by mere selection of proper width of coils and length of stack.

In spite of the simplicity of tests, certain precautions are necessary to secure correct results. In the case of wide coils, for example, it is imperative to measure voltages in different parts of each coil rather than limit these measurements only to turns located on the edges of the coils, as is frequently done. For instance, if on Fig. 10, a line were drawn over points marked *r* and *l*, which indicate the voltages on the outside and inside edges of coils, it would give quite a smooth curve which approaches the uniform distribution line. However, the actual distribution, shown by the solid wavy curve, is extremely non-uniform with the *middle* of each coil at much higher potential than its edges and with as much as 30 to 40 per cent of transformer terminal voltage appearing across half of a coil near the ground end of the stack.

In case measurements are made only on the outside edges, the difference between conditions indicated by such tests and the true conditions can be seen from a comparison of curves 1 and 1*a* of Fig. 13.

With the above in view, I ask Mr. Putman whether the curves shown in his Figs. 5, 6, 7 and 8 are the results of measurements made at the *middle* and at *both edges* of each coil.

Mr. Putman states that he uses a "static plate" but not a "shield." I should appreciate it if Mr. Putman were to give his definition of the word "shield" since, in the light of the above, it is obvious that, in case his tests indicate values measured on both edges and in the middle of each coil, such results could not be obtained without the use of some special means to neutralize, to a marked degree, the effect of ground capacitance.

Could Mr. Putman also tell us how essential is the presence of his "static plate" for securing distribution shown by the above curves? What would the distribution be without "static plates"?

Reduction in Major Insulation Stresses. The author of the paper points out that in the winding of Fig. 3 of his paper the dielectric field concentration at the edge of the line coil is not as high as in the old construction shown in Fig. 2. It is obvious that if the distances between the core and the line coil were made the same in the two constructions, the overall stress and the concentration of field on the winding of Fig. 2 (old design) would be less than that of Fig. 3, while the field concentration on the line coil will not change appreciably. The reduction shown in Fig. 3 is caused by a 30 per cent increase in distance between coil and core rather than by any improvement in construction. Since the voltage from line coil to core in both constructions is identical it is not clear why it was necessary to make such an increase.

Lightning Tests. It is stated in the paper that the lightning tests described therein were the most severe ever performed on assembled power transformers. I question the correctness of this statement. The tests we made about a year and a half ago (and reported at the time in the A.I.E.E. Transactions, January 1930) on one of the 13,000-kva., 230-kv. transformers built for the New England Power Co. consisted of over 200 impulses. Of these, over 40 were equal to or in excess of that necessary to arc over the 64-inch coordinating gap. Many were sufficiently high to arc over the transformer bushing. In Fig. 11 of this discussion are shown copies of the oscillograms of the most important waves used during these tests. Waves shown by dotted lines are taken from Dann's paper referred to by Mr. Putman

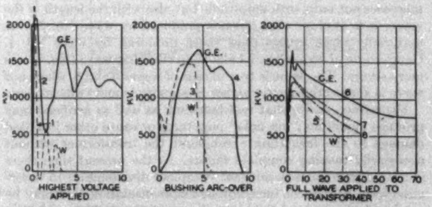

Fig. 11—Lightning Test on Core and Shell Type Transformers (230-Kv. Operating Voltage)

——— G. E. test August 1930 (core type)

— — — W test August 1931 (shell type) waves shown are applied to high-voltage terminal

(*Electric Journal*, Dec. 1931). Wave No. 5 was taken from Mr. Putman's lecture given at Hazleton last fall. Our waves are shown by solid lines. No. 2 was not previously published. No. 4 was published in the *G. E. Review*. A wave practically identical to No. 6 was also published in the same periodical.

Mr. Putman considers that the wave No. 1 was the most severe because it rose at the rate of 11,000,000 volts per microsecond. It would be easier to agree with him if he gave some experimental data showing the effect on insulation of rate of voltage rise. I believe that this impulse was not particularly severe because of its extraordinary shortness. It lasted only two tenths of a microsecond.

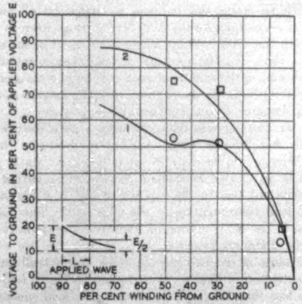

FIG. 12—MAXIMUM VOLTAGE TO GROUND PRODUCED BY WAVES WITH EXPONENTIAL TAILS OF DIFFERENT LENGTH (TEST RESULTS)

Length of wave in per cent of natural period of transformer 1—21 per cent (Palueff's test on core type transformer)
○ —22 per cent (Hodnette's test on shell type transformer)
2 —107 per cent (Palueff's test on core type transformer)
□ —113 per cent (Hodnette's test on shell type transformer)

Since it is recognized that the destructiveness of impulse waves increases not only with amplitude but also with the length of the wave, it is obvious that stresses produced by wave No. 2 were materially more severe than those produced by wave No. 1. Comparison of waves 3 and 4 also shows that our wave (No. 4) was more severe. The same is true in case of waves 5 and 6, where our wave is about 38 per cent higher in amplitude and twice as long.

Experience shows that real lightning as well as artificial may produce numerous "pin-hole" punctures or cause other localized damage to the insulation throughout the transformer without necessarily causing complete failure. At the present time there is no means available, without complete disassembly, to determine local damage of turn, coil or major insulation that may be produced by artificial lightning. I would like to know whether the 42,000-kva. transformers subjected to lightning tests by Mr. Putman were disassembled for minute examination of each coil and insulation parts.

For a number of years we have felt that the standard induced voltage test specified for grounded transformers was not an adequate test alone because the voltage stresses produced by such a test do not correspond either in magnitude or distribution to stresses produced by transient voltages in transformers of ordinary construction. This, in case of a grounded transformer for example, would permit building a transformer of given operating characteristics (and meeting all A.I.E.E. rules and tests) at a cost appreciably less than that of transformers designed to withstand transient voltage stresses. It is obvious that should lightning tests be made a part of A.I.E.E. acceptance test it would help to bring the standards of transformer design to a more uniform level.

For the above reason I heartily endorse Mr. Peek's suggestion made at the Convention, that the proper A.I.E.E. committee should consider the possibility of standardizing artificial lightning tests as a part of the acceptance tests on transformers, supplementary to the present induced voltage test of 3.46 times normal.

Effect of Length of Wave on Amplitude of Oscillations. Mr. Putman states "surges can not produce *severe* internal oscillations unless the duration of the surges is longer than the natural period of the transformer." A more accurate statement of this relation is as follows:

The voltage of any particular harmonic of transformer oscillation will not reach its *crest* value unless the length of the applied wave is at least half of the natural period of the harmonic.

W. M. Dann: In his paper Mr. Putman refers to shell type transformers with graded insulation, and this subject is discussed in the following.

About ten years ago Westinghouse engineers made an exhaustive series of tests to determine the distribution of surge voltage throughout the windings of shell type transformers of current design. In these tests, surges from a surge generator were impressed upon the high-voltage winding, and surge voltages to ground from various parts of the winding were measured with a sphere gap, as well as voltages between coils and between various parts of the windings. In those days we had no cathode ray oscillograph and it was not possible to reproduce a picture of the wave as it is done today. However, the shape of the wave was calculated from the constants of the circuit, and of course its magnitude could be measured directly with a sphere gap with a very fair degree of precision. It was on this basis that these distribution tests were made, first with a very steep wave having a long tail and then with a wave of less steepness decreasing to half value in approximately 20 microseconds. It took almost a year to complete them, and an idea of the thoroughness and care with which they were made may be gained from the fact that all results were checked by three of four different observers in repeated tests.

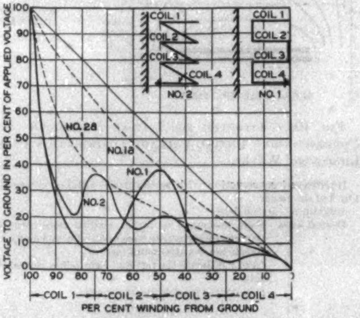

FIG. 13—INITIAL DISTRIBUTION IN A STACK OF FOUR VERY WIDE COILS

1 and 2—Actual distribution (voltages measured throughout the coils)
1*a* and 2*a*—Apparent distribution (voltages are not measured throughout the coils)

These tests showed very clearly that in the shell type transformer there were no dangerous voltages of the kind which one would expect if violent internal oscillations were developed by the entering surge. They furnished direct data on surge voltage stresses between winding and ground for the proper design of graded major insulation.

These actual tests supplemented in an important way the fundamental data on which Westinghouse design practises have been based. At the time they were made they were considered of prime importance; since then, they have become of great interest because of the repeated statements of Mr. Palueff and others to the effect that the practise of grading major insulation is hazardous.

That this practise is far from hazardous, I think, is clearly shown by the following facts:

1. There are more than three million kva. of 220-kv. Westinghouse transformers in successful operation with graded insulation, and the practise of grading the insulation for 220-kv. transformers is practically universal in this country.

2. There are approximately five million kva. of Westinghouse power transformers for 110-kv. and above in successful operation with graded insulation.

3. With all these transformers in service, to the best of our knowledge not a single failure of major insulation to ground due to lightning has been experienced in a Westinghouse shell type transformer having graded insulation; this record could hardly have been attained if dangerous voltages between winding and ground were actually set up by internal oscillations due to lightning surges.

References have been made at various meetings of the Institute by Mr. Palueff to the failure of a 220-kv. transformer at the Leaside station of the Hydro-Electric Commission at Toronto during a lightning storm. This transformer happens to be a Westinghouse shell type unit having graded insulation. These references appear on page 79 of the January 1930 TRANSACTIONS, and again on page 1195 of the July 1930 TRANSACTIONS, and once more on page 69 of the March 1931 TRANSACTIONS. In these references, this failure has been explained as a failure of the graded insulation to ground produced by violent internal oscillations, and it has erroneously been pointed to as an example of the hazard of grading the major insulation.

As a matter of fact, there was no failure of insulation to ground in this transformer. It was purely a failure across the high-voltage group of coils due to the presence of a tap lead, required for temporary 154-kv. operation, and this lead proved to have insufficient surge strength. It was not an inherent weakness due to the principle of grading the insulation, because the grading had nothing whatever to do with the failure.

The new surge-proof transformer, which Mr. Putman describes, represents a distinct forward step in methods of insulating, and in the practise of grading major insulation. Heretofore the insulation of a transformer having graded insulation has been graded by groups; that is, the high-voltage group nearest the line has been given the full amount of major insulation, and the group nearest the grounded end has been given a reduced amount of major insulation to correspond to the voltage stresses developed in the group, and intermediate groups, if any, have had an intermediate amount of insulation. I think Mr. Putman has made it plain in Figs. 3 and 12 and in the text of his paper, that in the new surge-proof transformer the coils themselves have been graded in width and the insulation around the individual coils has been graded in amount. The result is that concentrations of stress have been eliminated and the amount of solid puncture insulation around each coil has been proportioned to match the stresses developed in that coil.

It seems to me that the remarkable surge strength which has been demonstrated by the actual application of surges to these transformers shows the soundness of the principles on which the new design is based.

V. M. Montsinger: I discuss Mr. Putman's paper from the standpoint of 60-cycle and impulse arcover of barriers as affected by creepage. My experience does not check the data given in Fig. 10 showing no increase in the impulse arcover voltage for long collar extensions.

In the first place if the impulse strength shown as a practically horizontal line in Fig. 10 is correct, this shows that creepage strength across the edge of the barrier must be approximately the same as the puncture strength. This follows because the creepage certainly can be made great enough to cause puncture. Since the impulse strength curve is practically horizontal the two strengths; *i. e.*, creepage over edge and puncture, must be approximately equal. This does not seem reasonable.

Numerous tests have shown that for a practical barrier as used in design work puncture occurs at approximately twice the voltage at which arcover occurs when the electrodes are even with the edge. This is true for both 60-cycle and ½/5 microsecond impulse waves. It follows, therefore, that under these limiting conditions the impulse ratio is approximately the same.

Fig. 14 shows the results of tests made on a barrier with various creepage distances.

My experience in breaking down complete transformers shows that approximately the same impulse ratio is found whether failure is entirely by creepage or by a combination of puncture of solid insulation and creepage when using the ½/5 microsecond wave. This refers to cases where oscillations are not involved.

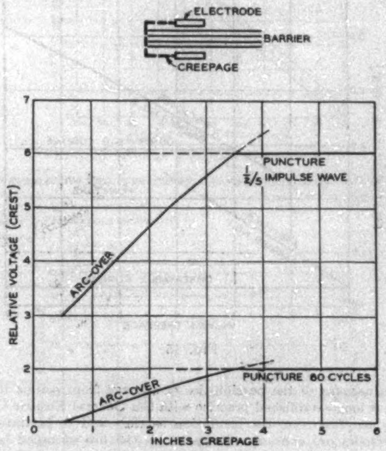

Fig. 14

I feel, therefore, that it would not be advisable to make any radical change in design practise as a result of the data given in Fig. 10 of Mr. Putman's paper.

So far my remarks have been confined entirely to breakdown, no reference being made to the appearance of corona in oil.

Fig. 15 illustrates the very wide range in 60-cycle voltage between the beginning of corona and the breakdown of two barriers of different thicknesses. These data show the importance of properly proportioning the barrier extension.

It is evident that the observable corona depends only on the thickness of the barrier and shape of the terminals; also that it is not of any use so far as suppressing corona is concerned to make the extension very much in excess of twice the thickness of the barrier.

If the barrier extension is many times its thickness and if the voltage is raised above the corona point, heavy local arcing may result in serious damage to the barriers long before arcover or puncture takes place. This is true of either 60-cycle or impulse voltage. For obtaining the data shown in Figs. 14 and 15 the electrodes were symmetrically located on both sides of the barrier.

To see if I could check the constant impulse voltage curve, shown in Fig. 10 of Mr. Putman's paper, tests were made on a barrier in oil as near like this one as possible. Fig. 16 shows that with a fast-chopped wave the impulse voltage increased quite definitely with an increase in extension. For the ½/5 full wave the voltage increased more than with the chopped wave. For a still slower wave the increase in impulse voltage was more marked. Mr. Putman did not define the wave he used. I would not say that the constant voltage *versus* creepage can not be obtained though I feel that a condition that gives this result is not a practical one.

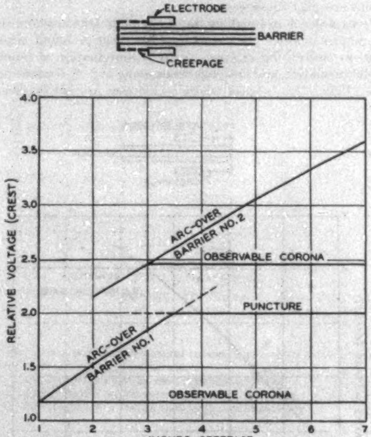

Fig. 15

On account of the possibilities of damage from corona it has been a long established practise with the General Electric Company to proportion the insulation barriers and to insulate the (electrodes or) ends of coil stacks by the use of taped buffer coils so that no corona occurs during any dielectric test. Dangerous corona in the oil usually results in the surface of the oil being disturbed.

In conclusion I want to emphasize two points—(1) that creepage distance if properly used can be depended upon for a certain insulation strength even with impulse voltage. (2) That no matter what tests on barriers show, impulse breakdown tests are finally made on complete transformer windings by testing them to destruction.

Transformers covering the complete voltage range have been tested to destruction in our laboratory by impulse voltage.

J. R. Gaston: Mr. Putman has obtained apparent success in building a surge-proof "pan-cake coil" shell type transformer. Unquestionably the design is successful between limits that will be shown. But to assume that the impulse tests signify, for this type of power transformer, the results in the degree that the paper seems to imply, fails to be impressive because of the omission of the following important data, namely:

1. *Polarity of Impulses*. An eleven-million-volt negative impulse is not necessarily as effective as a five-million-volt positive impulse. Both the paper and bibliography fail to give the polarity of the impulses.

2. *Temperature of Transformer*. The dielectric strength of both oil and fibrous material decreases with a rise in temperature, while their conductivity may increase several thousand fold or more in the operating temperature range of the average transformer. The paper does not give these data, and therefore from engineering point of view we must assume that the surge tests were made cold.

In commenting on Appendix II, it appears that explanations for Figs. 9 to 11 are in error, as follows, namely:

1. Breakdown creepage distance varies logarithmetically with the voltage, and not directly.

2. Fig. 11 would be correct if K for oil and the fibrous insulating materials were the same; the deduction being that unless the corners are heavily reinforced breakdown would result, and after all, that is the purpose of "angle rings" or "flanged collars" as used on core type transformers.

I agree with Mr. Palueff that under the present system of impulse testing the purchaser's property is more apt to be unnecessarily exposed to incipient breakdown, if tested hot, and I do not consider a negative cold surge test of much significance, with the present data available.

A. A. Emlen: In connection with the suggestion that the machinery committee investigate the possibility of incorporating in the Institute Rules a "surge test for transformers," I would offer the following comments:

It is not clear from the data given on surge tests as actually applied to transformers at what temperature these tests were made. Since the temperature of the dielectric, whether oil or solid, has a decided bearing on the voltage a transformer will stand (either 60 cycle or impulse) it would be interesting to learn whether the results obtained were at low temperatures or at 75 deg. cent.

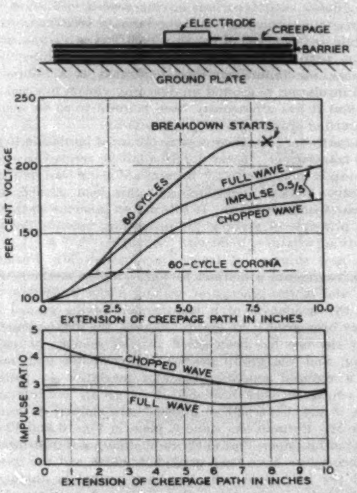

Fig. 16

If studies are to be made regarding surge tests for commercial transformers it seems that the temperature at which these tests are made is a very important point to consider.

Considerable progress seems to have been made in the development of apparatus to determine the existence of incipient corona or breakdown. However, till these detectors are practically foolproof it would not seem advisable to apply surge tests of any magnitude to commercial transformers.

J. Murray Weed: It is most gratifying to me to see the progress which has been made and which still is being made in the development of surge-proof transformers. When the pioneer paper on this subject was discussed by the Institute in 1922,[1] the consensus of opinion was that, although it possessed great theoretical interest, its application was either unnecessary or impracticable. In closing that discussion, I put the best face I could on the situation by saying, "I have gone as far as I have been able to go in pointing the way and I would not be surprised to see the application of the general method here illustrated carried much further than seems to be expected by most of those who have discussed the paper."

The designers of the transformer described in the present paper must be given credit for having made an approach to a uniform gradient for surge voltages in shell type transformers. It is interesting to observe that, however much the arrangement here shown appears to differ from any of those shown in my paper referred to or from the non-resonating transformers which have been built by others, the fundamental principle involved is the same in all cases. As stated in my paper, the method consists in so embedding the winding within the dielectric of a condenser, whose plates are connected to the winding terminals, that the potential imparted to each turn through the dielectric (by condenser action) corresponds to a uniform distribution of voltage from turn to turn. If, in this case, the line static plate and the tongue iron be recognized as the chief plate elements of the condenser and the plot of electrostatic field shown in Figs. 3 and 4 be completed to cover the region occupied by the winding, this will give a true picture of the initial surge voltage distribution. The potential of each turn would be indicated by its position with respect to the equipotential lines.

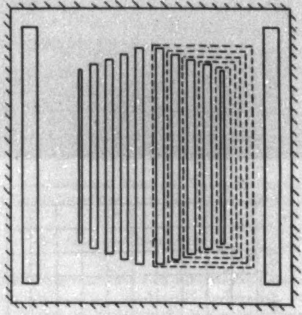

FIG. 17—SINGLE-GROUP SHELL TYPE TRANSFORMER DESIGNED FOR ELIMINATION OF CREEPAGE SURFACES

If the measurements of the surge voltages shown in Figs. 5 to 8 were made on the outside turns of the respective coils, the part of the field external to the coils would need some correction, of course, to correspond with the actual voltage distribution. If the whole field were correctly plotted, I fear that the location of the equipotential lines would reveal voltages on some of the interior turns of the coils which would fall a considerable distance from the curves in Figs. 5 to 8. It is readily seen, however, that the initial surge voltage distribution near line end of the winding has been improved by the introduction of the plate.

F. J. Vogel: The primary importance of Mr. Putman's paper rests in the principle that to obtain the highest impulse voltage strength, it is necessary to eliminate creepage surfaces. This is not a new principle, since in the insulation between the high- and low-voltage windings of all transformers, barriers of insulating material are common practise. What is new is the further application of this principle between coils of a single winding to increase the insulation strength of the winding to the greatest extent.

One of the most interesting features of this development is the broad extent of its application. It is not limited to designs using a single high-voltage group, nor even to designs with grounded neutral. It can be applied to transformers grounded through reactance at the neutral or fully insulated star- or delta-connected transformers. To demonstrate this, the possibility of elimination of creepage between coils of a shell type transformer winding capable of withstanding a high dielectric test to ground is indicated in Fig. 17.

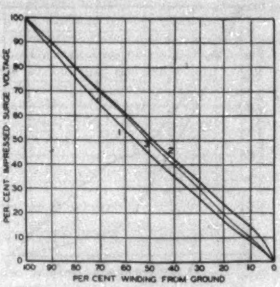

FIG. 18—SURGE VOLTAGE DISTRIBUTION

In single-group shell type transformer surge entering one end—1½—40 wave
Curve 1—Initial distribution
Curve 2—Maximum oscillation

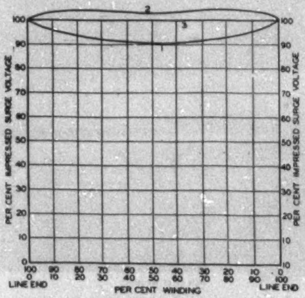

FIG. 19—SURGE VOLTAGE DISTRIBUTION IN SINGLE-GROUP SHELL TYPE TRANSFORMER

Equal surges entering both ends—1½—40 wave
Curve 1—Initial distribution
Curve 2—Maximum oscillation

The extent of the application of such a group as shown in Fig. 17 is very important. For example, the distribution of surge voltages is just the same, whether the surge comes in from either end of the winding due to the symmetry of its arrangement. Fig. 18 shows the initial distribution of voltage and maximum voltage to ground when the surge enters from one end, and Fig. 19 shows both the initial distribution and the maximum voltage to ground when equal surges enter both ends of the winding. Therefore, it is easily possible to apply this type of design to delta-connected transformers and obtain surge proof characteristics.

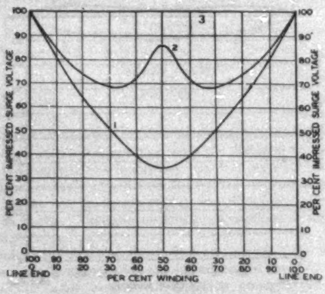

Fig. 21—Surge Voltage Distribution in Two-Group Shell Type Transformer

Equal surges entering both ends—1½—40 wave
Curve 1—Initial distribution
Curve 2—Maximum oscillation

It is but a step from the fully insulated single-group design, to the fully insulated two-group design. As previously brought out in a paper by Mr. J. K. Hodnette, (Trans. A.I.E.E., Jan. 1930, p. 68) if the surge enters from one line, nearly all the stress from the initial distribution will be concentrated in the one group, and will be nearly uniform in this one group. This is shown in Fig. 20. This one group can be made as resistant to insulation failure during the period of initial voltage distribution as the one group design previously described. The voltages to ground resulting from a long wave are also shown in Fig. 20. This shows that the stresses to ground at the middle of the winding will not be excessive, particularly since a wave as long as this will be much lower in magnitude than the very shortest ones. The initial distribution and maximum voltage to ground, for simultaneous equal surges on both ends of the winding, are shown in Fig. 21 taken from test data. Thus, the possible application of the design to delta connected transformers is clearly known.

One further step is the application of this principle to a grounded neutral design, but with insulation graded in proportion to the induced stress at the interleaved low-voltage coil and in the group connected to ground. Such an arrangement is shown in Fig. 22. The distribution within the winding for both short and long waves would be similar to that indicated in Fig. 20. Taking into consideration the relative magnitudes of such waves (approximately 14 to 7 times normal), it can be readily seen that the insulation at the interleaved part is not unduly stressed. (Fig. 23.)

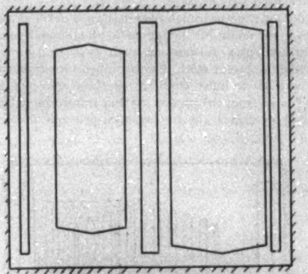

Fig. 22—Outline of Graded Insulation in a Two-Group Shell Type Transformer Eliminating Creepage

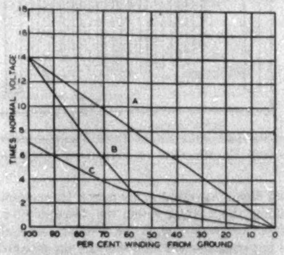

Fig. 23—Surge Voltage Distribution

Two-group shell type transformer with graded insulation
Curve B—Voltage in transformer due to highest line surges
Curve C—Voltage in transformer due to longest line surges (just low enough not to flash over line insulation)

The natural period of interleaved shell type transformer windings, although not in itself of great importance, is of interest due to its effect in reducing the magnitude of oscillation of such windings. A comparison of the oscillations within a single group, and also of an interleaved winding is shown in Fig. 20. The natural advantages of the shell form of construction are shown quite clearly by the fact that with a single group, good distribution is obtained, and hence the oscillation, although short in period and relatively completely developed is not important (Fig. 19). When interleaved, good distribution is obtained in the line group and the high ground capacity at the interleaving prevents high oscillation and also increases the natural period so that unless the surge is extremely long, the maximum oscillation can not be developed. For example the maximum potential by oscillation at the mid point of the winding as shown by Fig. 25 and by Fig. 20, curve 2, is 38 per cent of the impressed surge.

The curves of voltage distribution and oscillograms shown in this discussion were taken during the development of some 4,500 and 20,000-kva. transformers for the Pennsylvania Railroad. These transformers are single-phase and insulated for a 309,000-volt test from the high-voltage to low-voltage windings and ground. They are also designed to be co-ordinated with a 41-inch gap for impulse strength. To demonstrate this, the first transformers completed have been subjected to impulse voltage tests, with waves of both short and long duration. No indications of weakness either during the test or by complete disassembly and inspection of the units were found.

Fig. 24—Oscillogram Showing Voltages to Ground in a Single Shell Type Group at Points 1/3 and 2/3 from the Line End

No violent oscillations are indicated

Thus the application of the principle has been made to fully insulated transformers which are operated single-phase, and which could equally well be operated in delta.

H. V. Putman: Several of the discussors appear to be much concerned about the core-type transformer. They have rushed to its defense, but I have made no attack on it. My company builds core-type transformers—many more core types than shell. We recognize the merits of core type construction, but also its limitations. We recognize the merits and limitations of shell type construction also. Our engineering policy is to use the type best suited for any given application. Our development work for many years has been carried out on both types in parallel. We have done quite as much surge voltage investigational work on core types as on shell. We have millions of kva. of each type in service.

In discussing differences between core and shell, some of my critics are at a disadvantage, since their experience has been largely with core types. For instance, Mr. Clem condemns all shell type construction on the basis of experiments on ten round coils ten inches wide—a mere toy. Our knowledge of both core and shell types represents results on real transformers—some of them among the world's largest.

This background of parallel experience on both types places my associates, Bellaschi, Vogel, Fortescue and Hodnette, in a favorable position to speak authoritatively on the *differences in characteristics* of the two types.

Creepage Surfaces

Mr. Palueff's discussion is characterized by sketches representing his idea of Westinghouse transformers. These sketches are incorrect. No transformers have ever been built employing the winding arrangements shown in his Fig. 6, *B* and *C*, nor employing the insulation structure shown in his Fig. 7. He does not see why I prefer the new insulation arrangement, because, according to him, "creepage paths still exist at the top and bottom of the insulation structure (his Fig. 7), and the stress across these creepage paths is now three to eight times as great as in the old design." I prefer the new arrangement, because, based on actual tests, it has set a new standard of performance in the matter of resistance to surge voltages.

The insulation barriers employed in the new surge-proof transformers do not extend straight up above the coils (as in Mr. Palueff's Fig. 7), but they are turned over at the top substantially coincident with the equipotential surfaces. The creepage paths shown by Mr. Palueff and referred to by Mr. Peek therefore do not actually exist in the transformer. I fear neither of these gentlemen really understands what I mean by eliminating creepage surfaces. I mean simply the location of the insulation barriers so that their surfaces are substantially coincident with the equipotential surfaces of the electrostatic field. I do not claim to have enclosed each coil in a sealed box of insulation. It is, of course, possible to trace a devious path from one coil to any other coil. But with my arrangement, the direction of voltage stress is approximately normal to the insulation surfaces at all points, and this is the condition that gives the highest impulse strength.

Fig. 25—Oscillogram Showing Voltage to Ground at the Midpoint of a Two Group Shell Type Winding

Note long natural period of over 300 in. due to interleaved windings

Mr. Palueff states that in my new design I have crowded the full line-to-ground voltage into 1/3 to 1/8 the space used for it in the old. This statement is based on the winding arrangements imagined by Mr. Palueff in his Fig. 6, B and C, which, of course, never have been and never would be used. He appears to refer to the voltage lengthwise of the high-voltage stack, and presumably to the surge voltage, since there would be no question about the normal voltage. His statement would not be true even if the winding arrangements in his Fig. 6 were used, since in any case practically the whole surge voltage would appear across the group connected to the high-voltage line. This is due to the large ground capacity to the low-voltage coil group at the end of the first high-voltage group.

In any transformer there are only a few inches of space between the high-voltage winding and the low, and across these few inches the entire surge voltage exists. Here, indeed, is a high gradient. Mr. Palueff is greatly concerned about gradients of much lower value lengthwise of the high-voltage stack; why isn't he concerned about this high gradient in the few inches between the high and low? Simply because in these few inches lie puncture barriers separated by oil ducts—the best kind of insulation known. It is this kind of insulation—puncture barriers separated by oil ducts—that I have used throughout my entire insulation structure *lengthwise of the stack*, as well as between high- and low-voltage windings. The gradients through the barriers lengthwise of the stack are, of course, appreciably less than through the barriers in the space between high and low.

Both Mr. Montsinger and Mr. Palueff insist that creepage surfaces are entirely dependable if used intelligently within their limitations. I fully agree (we use them in our core type transformers), but is that any reason for not discarding them in favor of something superior wherever practical?

It is only when creepage surfaces are involved, that designers begin to compare gradients in different types of transformers and worry about volts per inch. These matters do not concern our new surge-proof transformers; they belong to the past.

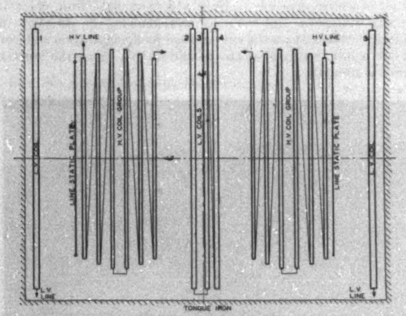

FIG. 26

Surges Induced in Low-Voltage Windings. I desire to correct a statement made by Mr. Palueff regarding the surge voltages induced in the low-voltage windings of shell type transformers. He states, "Another undesirable feature of the non-oscillating transformer of the interleaved type is the *extremely* high lightning voltage induced electrostatically in the low-voltage windings, from the high-voltage winding and static plate shown in Fig. 10. This happens because the low-voltage winding, instead of being placed next to the core, as in core type transformers, is placed in close proximity to the high-voltage line coil and static plate. From the approximate distribution of the electrostatic field produced by a lightning wave, Fig. 10, it follows that the low-voltage winding rises above ground to some 60 or more per cent of the amplitude of the lightning wave impressed on the high-voltage terminal."

It can be shown that this statement is incorrect. Of all the surge-proof transformers we have built, the 4,500-kva., 138-kv. fully insulated, single-phase transformers recently built for the Pennsylvania Railroad, had relatively the highest surge voltage induced in the low-voltage winding. These transformers have interleaved windings, as shown in Fig. 26.

Surely one could not conceive of a winding arrangement in which the low-voltage and high-voltage windings are more effectively coupled electrostatically. Having chosen the worst possible winding arrangement, let us also choose for investigation the worst possible case which occurs when a surge enters both high-voltage terminals simultaneously. Note that the high-voltage winding is not connected to ground at any point. Both ends are raised to the potential of the incoming surge and the remainder of the winding is free to float; closely coupled to it is the low. Even the terminals of the low are not solidly grounded but are connected to ground through 450 ohms to simulate the surge impedance of the low-voltage circuit. Under these conditions, let us examine the voltage induced in the low.

During the design of these transformers, Mr. Bellaschi made such an examination. His plot of the electrostatic field is shown in Fig. 27. The induced voltages shown by this plot are given in the figure. In Fig. 28 are also shown the test results for the potentials at all points in both the high and low voltage windings. It will be noted by reference to the table below that the maximum induced potential found in the low is 18 per cent of the lightning surge voltage as compared wtih 20 per cent calculated by Mr. Bellaschi.

CALCULATED AND MEASURED VALUES FOR VOLTAGES AT DIFFERENT POINTS IN THE L.V. WINDING

	Measured	Calculated
Coil No. 1—Line end	6%	
Coil No. 1—Finish Coil No. 2—Finish	15%	17%

It may be remarked that the measured values shown above were obtained by spark gap measurements between the various points in the winding and ground, and therefore represent maximum values, while the calculated values are for the initial voltages. However, it can be easily shown that under these conditions the maximum potentials in the low occur as a result of the initial distribution and not as a result of any subsequent oscillation.

Both the calculated and measured values reported above show that the surge voltages induced in the low of an interleaved shell type winding are not even of the same order of magnitude as Mr. Palueff believes.

In making his analysis, Mr. Palueff made the mistake of assuming that the potential of the points in the space occupied by the windings are unaffected by the presence of the windings themselves. He takes no account of the fact that the windings are made up of heavy copper conductors along which the charges may move—indeed, do move very appreciably in even a small fraction of a microsecond. When the presence of the windings themselves is taken into account, the shape of the field is materially changed, as can be seen from Bellaschi's sketch, Fig. 27, which is made correctly. In reaching conclusions in matters of this kind, practical experience with real transformers is desirable, since a superficial analysis can so easily be wrong.

In comparing the induced surge voltages in the low in core and shell type transformers, care should be taken to compare transformers of like specifications. For instance, Palueff says that in core types the low-voltage winding is placed next to the core, but in a core type transformer, to meet the low 4 per cent reactance required in the 4,500-kva. transformers, it is necessary to place a section of the low-voltage winding outside the high-voltage stack as well as next to the core. The low-voltage winding thus consists of two concentric cylinders with the high between the two. With this winding arrangement, which is common in core types, designed for low reactance, the electrostatic coupling between high- and low-voltage windings is quite as good as in an interleaved shell type. In our experience we have found that core and shell type transformers are on a par so far as surge voltages induced in low-voltage windings are concerned.

Distribution of Surges in Individual Coils. From the incorrect field plot in his Fig. 10, Mr. Palueff draws another surprising conclusion relative to the distribution of surge voltages within the individual high-voltage coils. He says, "However, the actual distribution shown by the solid wavy curve is extremely non-uniform with the middle of each coil at much higher potential than its edges, and with as much as 30 to 40 per cent of the transformer terminal voltage appearing across half of a coil near the ground end of the stack." This conclusion is, of course, absurd. Let Palueff refer to his own Fig. 13. According to the title, these curves represent actual measurements of the surge voltage distribution in a stack of four very wide coils. The voltage distribution within the individual coils is not uniform, and the distribution curves are characterized by what we call "saw teeth." The magnitude of these saw teeth is greater the fewer the number of coils in the group, so that in a group of only four, these saw teeth would be very pronounced.

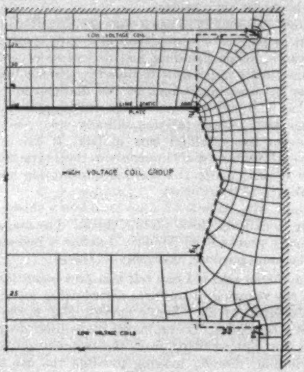

Fig. 27

An examination of these curves shows that the potential of the mid point of the coil at the ground end is about 5½ per cent for connection No. 1 and about 7 per cent for No. 2, instead of the 30 to 40 per cent mentioned earlier by Palueff. A further examination of these curves shows that in every case except coil No. 4, connection No. 1, the potentials at the mid points of the coils lie either in between those of the edges of the coils or else are lower; whereas Palueff concluded from his analysis, the potentials of the mid points would be *very much* higher than the potentials of the edges, as illustrated in his Fig. 10.

Effect of Coil Connections on Surge Voltage Distribution. Mr. Clem suggests that cross connections are hazardous and have been abandoned in shell type transformers. Mr. Peters' statement in this connection, quoted by Mr. Clem referred to transformers (core type, for instance), where the coils are spaced close together and sufficient room for properly insulated cross connections is difficult to obtain. In shell type transformers it is usually possible to obtain sufficient clearance for start-finish (or cross) connections and, in fact, this often results in the more economical winding. Our insulation tables cover both start-finish and start-start connections, and the designer employs the one best adapted to the particular design at hand.

In Mr. Palueff's discussion of Hodnette's paper referred to by Mr. Clem, Palueff claims that our results of surge voltage distribution were incorrect because we failed to measure the surge voltages on the *inside* edges of the coils and predicted that when we did so we would find the extremely non-uniform distribution claimed by him. Mr. Palueff's assumption in this case was unwarranted, because the measurements were made on a winding having start-finish connections, in which the inside edges of each coil are connected directly to the outside edges of each adjacent coil. Measurements were therefore made on both inside edges and outside edges simultaneously. Much of our early work was done with this type of winding because it did make it possible to measure the potentials on the inside edges. And it was the inside edge potentials in which we were vitally interested, because they established the potential distribtion along the creepage surface lengthwise of the group, along which failures took place when tests to destruction were made.

Uniform Distribution in Shell Type Stacks. Both Mr. Clem and Mr. Palueff discuss at great length the relative merits of core and shell type groups from the standpoint of initial surge voltage distribution. They present again the same old arguments and data which Mr. Palueff has repeated time and again in the A.I.E.E. discussions. These gentlemen apparently do not yet understand what we mean by saying that in a shell type group the surge voltage distribution is inherently substantially uniform. I am going to explain this statement very carefully and clearly. But before doing so, let us orient ourselves in this discussion to see what it is all about, and what practical conclusion it is desired to reach.

An ordinary transformer of either core or shell type construction, when tested to destruction with surge voltages, will usually fail lengthwise of the high-voltage stack, the failure starting at the inside edge of the line coil and extending along the creepage path on the insulation barrier adjacent to the coils. If the surge voltage stress is uniformly distributed along this creepage path, it is obvious that the maximum gradient will be lower and its resistance to breakdown will be greater than in a similar transformer, where the distribution is non-uniform. So the point under discussion is whether the distribution *along the creepage surface* lengthwise of the high-voltage stack is or is not substantially uniform in a shell type group. It is well known that the initial distribution along this creepage surface in a core type is extremely non-uniform, there being a very high gradient at the line end. Indeed, the use of shielding in a core type has as one of its principal objects, the elimination of this non-uniform stress distribution.

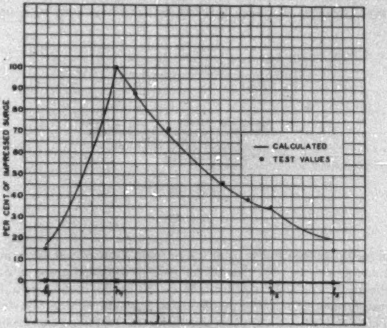

Fig. 28

But in an ordinary shell type, there appears still to be a difference of opinion about the uniformity of the gradient along this creepage surface. I shall therefore at this point present a careful explanation of this situation in a shell type group.

In Fig. 29 I illustrate a group of nine coils. In Fig. 4, Mr. Clem shows the initial distribution in such a group of nine coils for both start-finish and finish-finish connections. In an actual transformer of conventional construction, the line coil would have comparatively few turns heavily reinforced, so that the percentage of the total surge voltage appearing across it would not be as large as shown by Mr. Clem's curves, but the principle is the same and his curves will serve our purpose. In an actual transformer also, the duct space between the first two coils would be made larger than between the others, and additional insulation barriers employed in this duct.

The creepage surface in such a winding exists on the insulation barrier inside of the coils at the crown above the iron. It extends between points 2 and 4 as illustrated by the dotted line in Fig. 29. We have tested a number of conventional shell type transformers to destruction with surge voltages and they invariably fail along the path shown by the dotted line. We have never experienced a failure either across the face of the first coil nor between the first two coils at the outside, that is, between points 1 and 3, Fig. 29. The reason for this is that the great width of the shell type coil, which might be 20 or 30 inches in a large transformer, effectively protects the line coil against flashover. This width may often be greater than the length of the creepage path along the stack, so that there is not even a remote possibility of flashover across the face of the line coil. Furthermore, failures have not been experienced between points 1 and 3, Fig. 29, because there is no creepage surface here, solid insulation barriers being used, just as in the space between the high- and low-voltage windings. It is clear, therefore, that no difficulty has been experienced in insulating the first coil and duct for the surge voltages appearing across them.

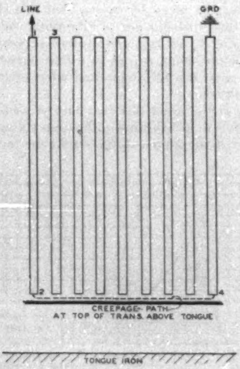

Fig. 29

The real problem in shell type transformers has been the gradient along the creepage surface just as in the core type.

In Fig. 30 I have plotted the voltage along this creepage surface, using the values from Mr. Clem's curves, Fig. 4, to illustrate the point that this gradient *is* substantially uniform. In plotting these curves, I have used the potentials on the inside edges of the coils which are adjacent to the creepage path and which establish the gradient along it, reading the data from Mr. Clem's curves.

These curves clearly show the uniformity of the gradient along the creepage path, which is characteristic of shell type groups. The difference between the two types is that in the core type this gradient is far from uniform, while in the shell type it is substantially uniform. The same result can be obtained from any of the other distribution curves for shell type groups presented by Palueff and Clem. With this point clearly established, let us examine its practical significance. It is this; shielding, however desirable in high-voltage core type transformers, would be totally ineffective in shell type so far as improving the dielectric strength of the creepage path lengthwise of the stack is concerned, since the gradient along this path is already uniform. And if any improvement is to be made in a shell type transformer, it must be made here, since this creepage surface is its weakest point. That improvement has been made a major improvement through elimination of the creepage surface itself. Shielding would obviously be worse than useless.

Mr. Palueff has sought to show that the distribution in a shell type is just as bad as or worse than in a core type; that a shell type, therefore, needs shielding just as bad as a core type; but that it is practically impossible to shield it. He has beclouded the entire issue by drawing curves of the distribution within the winding, that is, in and out among the turns, rather than along the creepage path, where failures actually take place. I believe this discussion has clarified this matter. It has shown that shielding could fulfill no useful purpose in shell type transformers. It has also shown clearly the logic of eliminating creepage surfaces in this type of transformer.

Static Plate. Mr. Palueff asks me to define a shield. Surely he is not going to call my static plate a shield. The static plate was patented many years ago by Moody. I define it just as he did and use it for the same purpose. I employ no shield.

Mr. Palueff also asks if I can tell him how essential the static plate is to the securing of uniform distribution along the stack. It is not essential at all. Clem's curves, Fig. 4 show this. Its slight effect is negligible. It eliminates the voltage drop across the face of the line coil resulting from the penetration of the surge into the winding, thereby making possible the use of ducts all of the same width and a uniform conductor insulation throughout. The use of a static plate with shell type transformers of conventional construction would result in general in lower impulse strength, because it would place the entire surge voltage across the creepage path lengthwise of the group, whereas without the plate this voltage across the creepage path *is* reduced by the voltage drop across the line coil. The line coil is much more able to stand this voltage than the creepage path.

Distribution in Core Type Stacks. Mr. Clem presents certain data in his Fig. 4 which show that the distribution along a stack of core type coils only two inches wide is substantially uniform. In fact, Fig. 4 shows a perfectly uniform distribution along the inside edges of the coils, and hence along the creepage surfaces. These data are, to say the least, most misleading. Surely he would not have any one ascribe any practical significance to such results. If he is correct, then transformer designers have been grossly misled these many years in reinforcing the insulation between coils at the line end of core type transformer windings and there is no purpose in Palueff's shielding. Such results can be obtained in a stack of coils without ground capacity, but not in a real transformer.

Surge Voltage Tests. I would like to say a few words about the relative severity of our lightning tests. My claim to first place was based on the G.E. published data relative to its New England power test. However, comparing data as Palueff has done in Fig. 11 is rather fruitless until it can be established why a Pittsfield volt is not as large as a Sharon volt. Our laboratories will no doubt eventually be able to measure the same voltage for the flashover of the same gap. At present, however, when dealing with short surges of the order of 5 microseconds, Pittsfield measures voltage from $\frac{1}{4}$ to $\frac{1}{3}$ higher than Sharon and

Trafford. Thus a given voltage measured by us as 1,500 kv. would be measured by Pittsfield as approximately 2,000 kv. If my test on the 42,000-kva. Baltimore Consolidated transformer were calibrated in Pittsfield volts, it would register close to 3 million volts, while our measurements indicated 2¼ million. This question might well have been deferred until the data published by our laboratories show better agreement.

Messrs. Paluett, Montsinger and Peek have all referred to the pinhole punctures between turns resulting from repeated surge voltage tests. This arouses my curiosity, because we have not found these in our experience. If such failures have actually been experienced, it must indicate some weakness in conductor insulation. We have built and tested experimentally many full size power transformers. Some of these were tested to destruction, others not; in all cases they were torn down and examined. Many were rebuilt, retested, and re-examined the second time. In some cases our coils were examined under a magnifying glass in an effort to find some of these pinholes, but without success.

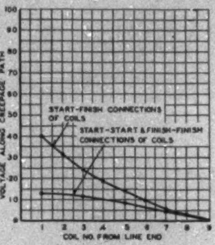

FIG. 30

I might say also that in all of our experience in testing shell type transformers to destruction with surge voltages, we have never seen a coil fail across its face. There need be no concern about the unequal distribution of surges within individual coils.

Mr. Palueff asks if we have torn down and examined commercial transformers after impulse tests. The Baltimore transformer, on which the measurements of distribution within the winding were made, was torn down sufficiently to attach the necessary connections between coils. We were able to examine those parts of the insulation structure which our experience had indicated would be the first to show any marking. Every piece of insulation was clean.

Some of the 4,500-kva. fully insulated transformers mentioned previously were disassembled and minutely examined. One of these transformers was given a total of 106 surges, all above the flashover of the protective gap. On one occasion the coils and insulation were laid out on the assembly floor, where they were examined by a party of 40 or 50 visiting engineers.

If was after making a number of successful surge voltage tests on commercial transformers that we recommended early last fall to the N.E.L.A. the use of surge tests to demonstrate guarantees of impulse strength. I am glad to see that others are now also coming to recognize that low-frequency dielectric tests do not constitute any demonstration of impulse strength and to agree that surge tests are practicable. I feel sure that we have already reached a satisfactory solution to the problem of failure detection mentioned by Mr. Peek.

Messrs. Gaston and Emlen ask about the temperature at which impulse tests have been made. All of our commercial transformers have been tested hot. Tests on our experimental transformers have been made both hot and cold.

Corona. Messrs. Montsinger and Peek mention the undesirability of corona during the low-frequency test. Since high-voltage transformers came into use, we have been building trnasformers which in all probability have some slight corona during the high-voltage test. Our experience is that in some types of insulation the corona point is very close to the breakdown point. Here the presence of corona during test would indicate overstressed insulation, and we are careful to avoid it. On other types of insulation structures, the corona point occurs at a much lower voltage than breakdown, and here slight corona during test need give no alarm. Copious corona discharges will usually produce visible marking on the insulation, and should, of course, be avoided. Experienced witnesses, who have seen insulation tests on many transformers of different makes, have often complimented us on the quietness of our transformers during the insulation test and on the lack of disturbance in the oil.

Barrier Test. I am much interested in Mr. Montsinger's comments on the barrier test. I went through the same process of reasoning myself at first and concluded that the impulse strength must increase with barrier extension. But repeated tests with very short surges (we used 1 microsecond or less) showed only very slight increase. Fig. 31 shows a complete set of time lag curves for barriers 1 inch thick, and with different extensions. These curves converge together for the very short waves, giving the result indicated in Fig. 10 of my paper. Mr. Montsinger's curve of impulse ratio against extension shows that the impulse ratio varies from 4.5 for zero extension to 2.7 for 8 inches extention for a ½-5 wave. With a much shorter surge, my Fig. 10 shows the impulse ratio to vary from 4.5 to 2. With surges of the same length, our data would not be far apart.

Internal Oscillations. Mr. Dann's discussion answers this question of internal oscillations in shell type transformers effectively, and I hope finally. One of the important differences between core type transformers and shell type transformers having interleaved windings is the long, naturel period of the latter, which effectively prevents internal oscillations of high magnitude. As an example, the natural period of the 4,500-kva. transformers previously mentioned was found from test to be 300 microseconds.

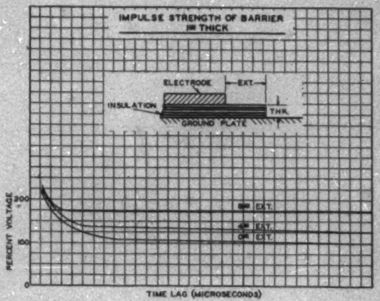

FIG. 31

Fully Insulated Transformers. One of the fine things about the improvements in shell type transformers which I have described is that they are in no way limited to grounded neutral transformers. Mr. Vogel in his discussion shows their application to fully insulated transformers and to transformers of the interleaved type.

Conclusions. The following paragraphs present a few important facts on which there is no difference of opinion. Core type transformers of conventional construction are characterized by an extremely non-uniform distribution of surge voltage lengthwise of the coil stack with high concentration at the line, and by relatively severe internal oscillations which produce correspondingly severe voltage stresses in the major insulation between high- and low-voltage windings, even with fairly short surges. These characteristics are recognized by all manufacturers of core type transformers, and the design of the insulation is made to take account of them.

There are two schools of thought regarding the best method of handling these core type insulation problems. One is represented by Palueff and his associates, who advocate graded insulation and the use of shielding to secure uniform distribution and prevent internal oscillations. The other is represented by European engineers, who prefer to utilize the space required by the shielding structure for full major insulation between high and low, and properly to reinforce the end turns rather than insulate a shielding structure at line potential from the entire high-voltage winding. This reinforcement or padding of end turns and coils insulates for the non-uniform initial distribution. The use of major insulation provides adequate dielectric strength against internal oscillations. The European engineer attempts to know the surge voltage stress at every point in his winding and to insulate for it directly. This is sound engineering and its simplicity commends it.

Both schools of thought are one in recognizing these insulation problems in core type transformers. They differ only in the method of solution advocated. For low-voltage transformers, the simpler European method of solution is used universally. It is in the higher voltage classes that these insulation problems become paramount and require careful consideration.

In these higher voltage classes we prefer to avoid entirely these difficult insulation problems by employing the simple construction disclosed in my paper. Reinforcement of insulation on end turns and coils is not required because the distribution of surge voltage stress throughout the entire insulation structure is substantially uniform and there is no creepage surface to protect. Where grounded neutral operation is required, graded insulation can be utilized with perfect assurance because severe internal oscillations cannot occur.

The simplicity of this new construction is apparent. Our claims of surge strength are backed by sound theoretical analysis and by tests on complete transformers. Operating engineers are not likely to be impressed by purely theoretical discussions. Only by actual demonstrations with surges representative of those produced by natural lightning will they be convinced of the surge-proof qualities of transformers.

Effect of Transient Voltages on Power Transformer Design—IV

Transition of Lightning Waves from One Circuit to Another Through Transformers

PART I—BY K. K. PALUEFF*
Member, A.I.E.E.

PART II—BY J. H. HAGENGUTH*
Associate, A.I.E.E.

Summary of this and preceding papers.*—Three preceding papers of the same general title have dealt with transient voltage stresses developed within high-voltage transformer windings. The most important conclusions arrived at by the author and presented in these papers and the discussions are:*

1. Transformers of all conventional constructions undergo oscillations when subjected to lightning or switching surges.

2. The amplitudes of these oscillations may be dangerously high, depending on the amplitude and the shape of the applied voltage. Their frequencies range from a few thousand to a few hundred thousand cycles per second.[1,2]

3. A lightning wave of a given shape produces very different stresses in different transformers. [1,2]

4. In practical design, neither amplitude nor frequency of these oscillations can be controlled by arrangement or proportions of windings.[1,2]

5. A lightning wave chopped by flashover of line insulation can produce stresses in transformer windings equal to or even in excess of those produced by a long wave of the same amplitude and front. [1,2]

6. Unless means are taken to obtain uniform distribution under all lightning conditions it is entirely possible to design transformers that will pass A.I.E.E. test which are inadequate for service conditions. This follows because test voltages in neither magnitude nor distribution of stresses correspond to that produced by transient voltages in transformers of ordinary construction. This difference is particularly great in transformers with solidly grounded neutrals, where the potential test allows the insulation from high-voltage winding to low-voltage winding and ground to be reduced as the neutral is approached.[1,2]

7. If a transformer winding is equipped with a properly designed electrostatic shield, voltages of all surges will distribute uniformly, and oscillation or resonance will not occur. Over 2,000,000 kva. of such non-resonating transformers are in successful operation.[1,2,4]

To demonstrate the lightning strength of such a transformer, one of fourteen 13,000-kva., 230-kv. transformers was subjected to artificial lightning in August 1930.[4,10] *Over 200 high-voltage surges were applied. Forty were in excess of the flashover voltage of the 64-inch coordinating gap. The majority of these were full waves just below the flashover of a string of 14 standard suspension insulators. A few were full waves just below flashover of the transformer bushings. Also a few waves high enough to flash over the bushing were applied. To be certain that no damage was done by these tests the transformer was completely disassembled for examination, since there is no other positive practical method available at present for determining a partial or local damage to the insulation inside of the windings that may be caused by lightning tests. These tests were preceded and followed by complete A.I.E.E. Acceptance Tests, including a 460-kv. induced potential test.*

8. A neutral impedor has been developed, extending the application of non-resonating design to transformers with partially or entirely isolated neutral.[3]

9. A non-resonating design has been adapted to auto-transformers.[5]

10. It has been shown theoretically and later experimentally, that a choke coil is worthless as a protective device, and may actually increase stresses.[1,2]

In this paper, the phenomena of the transmission of voltage surges through transformers to the connected secondary circuits are critically examined, a quantitative theory for their calculation is developed, and general conclusions on their magnitude are presented.

Part I

INTRODUCTION

THE impact of a surge on the high-voltage terminals of a transformer produces transient voltages not only within that winding, but also within the low-voltage winding, as well as at its terminals. The latter voltage is impressed on the network and apparatus connected to this winding and is the subject of this paper.

Some occasional failures, during lightning storms, of rotating apparatus connected to lines through transformers, indicate the possibility of transmission of high-transient voltages through transformers.

Dry insulation used in rotating machinery has much lower impulse strength than transformer insulation for the same operating voltage. On account of this it is more difficult to protect generators from transient voltages than transformers.

The first part of the paper deals with the subject from a practical standpoint. It establishes certain approximate relations between circuit constants, that are generally available, and transient voltages.

The second part is the mathematical treatment of some of the problems dealt with in the first. It shows first: that the approximations used in the first part are justified; second that in some cases these approximations are unavoidable because in practise most of the constants of the complete equations ((**1a**) for example) can not be determined.

FOUR COMPONENTS OF TRANSIENT ON THE SECONDARY CIRCUIT

It is convenient to consider that the surge voltage produced at the low-voltage terminals of a transformer by a rectangular traveling wave is a result of superposition of four components. Fig. 1.

1, 2. See Bibliography.

Presented at the Winter Convention of the A.I.E.E., New York, N. Y., January 25-29, 1932.

1. At the moment of impact of a lightning wave, an *electrostatic* voltage is produced at the terminals of the low-voltage winding which depends upon the relation of the distributed capacitances of the low-voltage winding to high-voltage winding and ground, and is independent of turn ratio.

2. A *free oscillation in the high-voltage winding*, consisting of a number of space harmonics,[1,2] induces a corresponding oscillation in the low-voltage winding. The induction is accomplished by means of the electrostatic and electromagnetic fields of these harmonics, and is dependent upon the distributed constants and turn ratio of the windings.

3. A *free oscillation in the low-voltage winding* follows immediately after the impact of the wave. The resulting voltages depend upon the distributed constants of the low-voltage winding.

4. Through a *purely electromagnetic induction* between the two windings, a unidirectional surge is produced on the secondary circuit. Its voltage rises from zero to a certain maximum, then decays to zero. The voltage is directly proportional to the turn ratio and is independent of the distributed capacitance. It is a simple function of the short-circuit inductance of the transformer and of the surge impedances of external circuits.

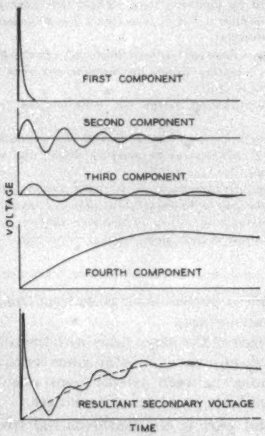

FIG. 1—SECONDARY TERMINAL VOLTAGE AND ITS FOUR COMPONENTS

All four components depend, to a different degree, upon surge impedances and lengths of external circuits connected to the transformer.

RELATIVE IMPORTANCE OF FOUR COMPONENTS

Let $2E$ be the voltage produced across the high-voltage ("primary") winding of a transformer by a rectangular wave of E volts and of infinite length, E_2' the crest voltage of the wave transmitted to the low-voltage ("secondary") circuit, Z_1 and Z_2' the surge impedances of external circuits connected respectively to the primary and secondary of the transformer, t_2' the *total* length in microseconds of the transmitted secondary wave, and t_1 the length of primary wave which would contain the same amount of energy as the secondary wave. It is assumed that the secondary circuit is at least $t_2'/2$ microseconds long.*

It can be shown that for an exponential secondary wave with a sheer front and a tail that falls from E_2' to $E_2'/2$ in t_2 microseconds, the maximum secondary voltage is

$$E_{2e}' = 0.59 \times 2E \sqrt{\frac{Z_2' t_1}{Z_1 t_2}}$$

Similarly, for a secondary wave, half of a cycle of a sine wave in shape with a length t_2 during which the amplitude is above $E_2'/2$, it can be shown that

$$E_{2s}' = 0.58 \times 2E \sqrt{\frac{Z_2' t_1}{Z_1 t_2}} \cong E_{2e}'$$

While for oscillatory secondary voltage which falls to zero in say five cycles, the crest voltage of the first half of a cycle is

$$E_{2o}' = 0.41 \times 2E \sqrt{\frac{Z_2' t_1}{Z_1 t_2}} = .71\, E_{2e}'$$

Voltages produced by the first and the fourth components are exponential and those produced by the other two are essentially sinusoidal and oscillatory.

Simple calculations show that for each of the first three components, t_1 is less than *two-* or *three-tenths* of a microsecond. It follows that t_2 for a given component must be exceedingly short to permit that component to produce a secondary voltage that is comparable to $2E$. (Fig. 2.)

Fig. 2 permits estimate of maximum possible secondary voltage where order of magnitude of t_2 is known. It also gives the maximum possible length t_2 of the secondary wave where its crest is known.

Under the assumption that the primary circuit is an overhead transmission line, curve 4.0 corresponds to a case where the secondary circuit is a winding of a small rotating machine, curve 1.0 where it is an overhead transmission line, and curve 0.1 where it is an underground cable. The range of large rotating machines is between the last two curves.

Time t_2 is materially shorter for the first component than for the second or third, due to the difference in the nature of these transients, but generally speaking the energy (proportional to t_1) involved in the first component is somewhat less. The value t_2 for the first com-

---

*By the "length" of a given circuit is meant the length of *time* T_1 required for a traveling wave to traverse the circuit from end to end. In one microsecond, a wave travels 1,000 ft. on an overhead transmission line and about 500 ft. on an underground cable. Propagation along a generator winding depends on many design factors, and is of the order of 100 ft. per microsecond.

ponent ranges between a fraction of a microsecond and say 5 microseconds. Furthermore, since the voltage of this component is induced purely electrostatically it obviously can not exceed the voltage applied to the primary ($2E$) but is a fraction (K_e) of this voltage. K_e depends only on the electrostatic relation of windings. The voltage produced by the first component becomes more dangerous as the rated secondary voltage, and correspondingly the insulation of secondary apparatus are reduced, because the voltage of the transmitted wave is independent of the turn ratio.

The time t_2 for the second and third components is relatively long, being in the order of a few microseconds to several hundred microseconds, particularly in a case where energy of these components can not be transmitted to the secondary circuit in one-half cycle of their respective frequencies as generally is the case. Keeping in mind the fact that t_1 in each case is a small fraction of a microsecond (t_1 of the second component is much greater than t_1 of the third), it follows from the equations above that E_2' for these two components must be a very small fraction of $2E$, Fig. 2.

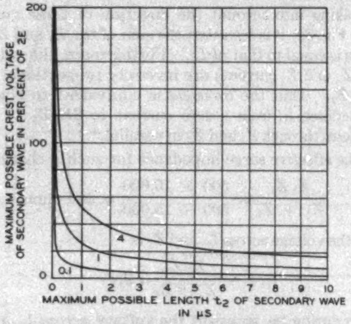

FIG. 2—RELATION BETWEEN THE MAXIMUM SECONDARY VOLTAGES AND THE MAXIMUM LENGTH OF THE SECONDARY WAVES CONTAINING THE SAME AMOUNT OF ENERGY

Curves based on: $t_1 = 0.2$ microseconds. Numbers on curves indicate the corresponding value of Z_2'/Z_1

Thus it appears that under average service conditions it is possible but not probable that secondary waves of high amplitude may be produced by the second and the third components of the secondary transient. However, high voltages may be produced if Z_2' is abnormally high or if the secondary winding is not connected to its network.

The amount of energy that can be transmitted to the secondary network by the fourth component may reach the order of magnitude of that contained in a *few hundred* microseconds of the primary wave. If t_2 were small compared to t_1, it would follow that E_2' could be many times E. However, the mechanism of creation of the secondary wave of this component, is such that t_2 is necessarily greater than t_1, to the extent that E_2' is never more than $2E/r$ in case the secondary circuit is sufficiently long and $4E/r$ in case the secondary circuit is very short (r is the ratio of turns of the primary winding to the secondary winding). It is seen, therefore, that very powerful secondary surges of dangerously high voltage can be produced by purely electromagnetic transformation of a lightning wave.

Where the secondary circuit is short in comparison with the length of secondary wave voltages in excess of those of Fig. 2 can be produced.

ELECTROMAGNETIC TRANSFORMATION OF TRAVELING WAVES

A. Single-Phase Transformer

1. Infinite Rectangular Traveling Wave

If the secondary winding were perfectly interlaced with the primary, then when a rectangular wave of infinite length is applied, the secondary voltage would rise instantly to a value equal to the primary voltage divided by the turn ratio.* The voltage of both windings would fall gradually to zero as the current in the primary circuit increases and approaches a certain constant value.

In an actual transformer, however, there is considerable leakage or "short-circuit" inductance between the two windings. This causes the shape, and to a small extent the amplitude of the secondary wave to be different from that stated above. The rise of voltage is not instantaneous, but requires from a fraction of one microsecond to a few hundred microseconds.

For the analysis of the electromagnetic transient it is convenient to think of it as consisting of two parts. The first is the comparatively rapid rise of secondary voltage. This is dependent almost entirely upon the *short-circuit inductance* L_s of the transformer, and will be referred to as the L_s transient. The second is the comparatively gradual decay of secondary voltage to zero. This is dependent almost entirely upon the *self inductance* L_1 of the primary winding, and will be referred to as the L_1 transient.

As is customary for mathematical analysis and laboratory tests, surge impedances of transmission lines, cables, generator windings, etc., may be replaced with resistances of equal ohmic values, and the voltage E of the traveling wave replaced by a d-c. voltage of $2E$. This permits the circuit consisting of the transformer (with both windings grounded) and its primary and secondary surge impedances, (Fig. 3a) to be replaced by that in Fig. 3b. The application of this method in the laboratory has known limitations which, however, do not apply in this case.

---

*The effect of mutual inductance on transient phenomena is well known. The mathematical derivations and resulting equations however are quite complex and difficult to visualize. Here, by taking advantage of relative values of transformer constants affecting the phenomena, the solution is arrived at in a most elementary manner. The results obtained agree very closely with the exact solution given in Part II.

To take care of the effect of turn ratio between primary and secondary windings, all of the constants of the secondary circuit may be replaced by equivalent constants which would produce the same effects in the primary circuit if the turn ratio were unity. This requires that the actual secondary surge impedance Z_2' be replaced by an equivalent value Z_2 which is equal to $Z_2'r^2$. Also this permits the circuit to be redrawn as in Fig. 3c, in which L_1, L_2 and M are respectively the self inductance of the primary and secondary (equivalent) windings and the mutual inductance between them. This may be simplified to the approximate equivalent circuit of Fig. 3d.

After a solution is obtained for an equivalent circuit, all secondary current and voltage values (I_2 and E_2) *must be corrected by the turn ratio to obtain actual values* (I_2' *and* E_2') *for the secondary circuit.*

To make the analysis more concrete, it will be followed in parallel with a numerical example. E is assumed to be 500,000 volts, Z_1 is 500 ohms. Single-phase transformer, 60 cycles, 22,500 kva., 66,000 volts (115,000 volts Y) to 13,200 volts, 6 per cent leakage reactance, L_s = 0.031 henrys, L_1 = 0.31 henrys, r = 5, Z_2' = 600 ohms, Z_2 = 25 × 600 = 15,000 ohms.

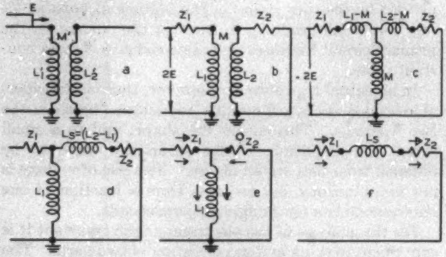

FIG. 3—DEVELOPMENT OF EQUIVALENT CIRCUIT FOR SINGLE-PHASE TRANSFORMER

⬅ Final current ← Transient current

L_1 Transient. Neglecting the effect of leakage inductance, it becomes possible to investigate the L_1 transient alone (See Fig. 3e).

At the moment of impact of a rectangular wave, L_1 acts as an open circuit because of the steepness of the front of the wave. A current equal to $2E/Z_1 + Z_2$) = (2 × 500,000)/(500 + 15,000) = 64.5 amperes will flow through Z_1 and Z_2, and no current will flow through L_1. The voltage across Z_1 will be $2E\ Z_1/(Z_1 + Z_2)$ = 64.5 × 500 = 32,250 volts. The voltage across Z_2 and L_1 will be $E_2 = 2E\ Z_2/(Z_1 + Z_2)$ = 64.5 × 15,000 = 967,750 volts. These are called initial values.

With $2E$ maintained sufficiently long across the circuit, a constant current will finally be established through it. To such a current the reactance of L_1 will be zero. Therefore, all the current will flow through L_1 and none through Z_2. The full voltage $2E$ or 1,000,000 volts will appear across Z_1 and no voltage will appear across L_1 or Z_2. The current through Z_1 and L_1 will be $2E/Z_1$ = 1,000,000/500 = 2,000 amperes, and that through Z_2 will be zero. These are called the *final* values.

Since the amplitude of the transient currents and voltages is the *difference* between the final and initial values, it follows that the amplitudes of transient currents are:

$$\text{in } Z_1,\ \frac{2E}{Z_1 + Z_2}\left(\frac{Z_2}{Z_1}\right) = \frac{2 \times 500{,}000}{500 + 15{,}000}\ \frac{(15{,}000)}{500}$$

$$= 1935.5 \text{ amperes}$$

$$\text{in } Z_2,\ \frac{2E}{Z_1 + Z_2} = \frac{2 \times 500{,}000}{500 + 15{,}000} = 64.5 \text{ amperes}$$

$$\text{in } L_1,\ \frac{2E}{Z_1} = \frac{2 \times 500{,}000}{500} = 2{,}000 \text{ amperes.}$$

Taking into account the direction of these currents (See Fig. 3e) it is seen that the sum of the Z_1 and Z_2 currents is equal to that of L_1. Furthermore, the values of the Z_1 and Z_2 currents are inversely proportional to Z_1 and Z_2. Thus the *transient* is equivalent to charging inductance L_1 from a zero current to $2E/Z_1$ = 2,000 amperes through Z_1 and Z_2 in parallel.*

The effective surge impedance for such a charge is

$$\frac{Z_1\,Z_2}{Z_1 + Z_2} = \frac{500 \times 15{,}000}{500 + 15{,}000} = 484 \text{ ohms}$$

and the voltage across L_1 and Z_2 is

$$E_2\, e - \frac{Z_1\,Z_2}{Z_1 + Z_2}\, t/L_1$$

Thus during the transient the voltage across L_1 and Z_2 falls exponentially from $E_2 = 2E\ Z_2/(Z_1 + Z_2)$ = 967,750 volts to zero. (Curve 1, Fig. 4.) From the laws of exponential functions, the voltage falls 95 per cent of this value in

$$T_1 = \frac{3\,L_1}{\dfrac{Z_1\,Z_2}{Z_1 + Z_2}} \text{ seconds} = \frac{3 \times 0.31}{484} \text{ seconds}$$

$$= 1{,}860 \text{ microseconds.}$$

L_s Transient. As was previously stated, the leakage inductance L_s (See Fig. 3d) prevents the voltage across Z_2 from rising instantly to its maximum value. During the time required for this voltage to rise only an exceedingly small current has time to build up in L_1, due to the fact that in transformers L_1 is generally much larger than L_s. For the analysis of the L_s transient this small current can be neglected and the equivalent circuit becomes that of Fig. 3f.

---

*This is in accordance with one of the useful rules of transients which permits an imaginary short-circuiting of all points between which voltage of a given transient is zero during the entire period. In this case voltage between terminals 1 and 2 is maintained constant ($2E$) and therefore has no transient component. This rule alone permits writing the expressions for E_2 and T_1 directly from inspection of the circuit of Fig. 3a.

Since the front of the incident wave is infinitely steep, at the first instant the entire applied voltage appears across L_s, and none across Z_1 and Z_2. No current will flow. This is the *initial* condition.

With $2E$ maintained sufficiently long across the circuit, the current will increase and approach a constant value. To this constant current L_s will offer zero reactance. The full voltage $2E$ will appear across Z_1 and Z_2 in series, and the current through them will be $2E/(Z_1 + Z_2) = 2 \times 500{,}000/(500 + 15{,}000) = 64.5$ amperes. The voltage across Z_2 will be $E_2 = 2E\,Z_2/(Z_1 + Z_2) = 2 \times 500{,}000 \times 15{,}000/(500 + 15{,}000) = 967{,}750$ volts. This is the *final* condition.

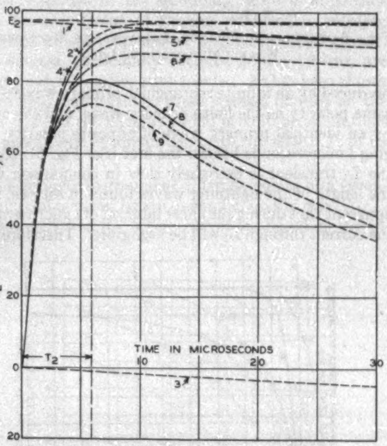

FIG. 4—SECONDARY TERMINAL VOLTAGE AS OBTAINED FROM EQUIVALENT CIRCUITS OF FIG. 3 FOR THE NUMERICAL EXAMPLE

Infinite rectangular primary wave
1. Voltage across Z_2 due to L_1 transient
2. Voltage across Z_2 due to L_s transient
3. Difference between curve 1 and E_2
4. Resultant secondary voltage obtained by superposition of curves 2 and 3

5 and 6. Resultant secondary voltage (using limits of $L_1 = M$ and $L_2 = M$ respectively) obtained by rigorous solution of circuit Fig. 3c (equation (2), Part II)

Twenty-five microsecond exponential primary wave
7. Resultant secondary voltage in circuit of Fig. 3f

8 and 9. Resultant secondary voltage for circuits Fig. 3c
(8) $L_1 = M$ (9) $L_2 = M$ (equation (9a), Part II)

Since the transient is caused by the *difference* between the final and initial conditions, the amplitude of transient current is $2E/(Z_1 + Z_2)$ and the amplitude of transient voltage across Z_2 is $2E\,Z_2/(Z_1 + Z_2)$. The transient consists therefore of charging the inductance L_s from a zero current to $2E/(Z_1 + Z_2)$ through Z_1 and Z_2 in series. It follows that the transient voltage across Z_2 rises exponentially from zero to $2E\,Z_2/(Z_1 + Z_2) = 967{,}750$ volts. It will reach 95 per cent of its ultimate value in $T_2 = 3L_s/(Z_1 + Z_2) = 3 \times 0.031/(500 + 15{,}000)$ seconds or in 6 microseconds. Thus,

$$e_2 = 2E\,\frac{Z_2}{Z_1 + Z_2} - 2E\,\frac{Z_2}{Z_1 + Z_2}\,e^{-\frac{Z_1 + Z_2}{L_s}t}$$

$$= E_2\left(1 - e^{-\frac{Z_1 + Z_2}{L_s}t}\right) \qquad \text{Curve 2, Fig. 4}$$

Resultant Z_2 Voltage. The voltage across Z_2 would be as shown by curve 2, Fig. 4 if the ultimate voltage across Z_2 were E_2. However, on account of the presence of L_1 the voltage across Z_2 gradually falls below E_2 and finally reaches zero (curve 1, Fig. 4). Therefore, voltage across Z_2 at any moment will be lower than that shown by curve 2 by the amount very nearly equal to the difference between E_2 and curve 1, *i. e.*, by:

$$-\left(E_2 - E_2\,e^{-\frac{Z_1\,Z_2}{Z_1 + Z_2}t/L_1}\right) = -\,E_2\left(1 - e^{-\frac{Z_1\,Z_2}{Z_1 + Z_2}t/L_1}\right)$$

(curve 3, Fig. 4).

The resultant voltage across Z_2 therefore (curve 4, Fig. 4) is obtained by superposition of curves 2 and 3 of Fig. 4.

$$i.\,e.,\ e_2 = E_2\left(e^{-\frac{Z_1\,Z_2}{Z_1 + Z_2}t/L_1} - e^{-(Z_1 + Z_2)\,t/L_s}\right)$$

Compare this with exact solution equation (**1b**) and (**2**) of Part II.

It can be stated that the secondary voltage is essentially a copy of the voltage across the primary terminals reduced by the turn ratio (curve 1 of Fig. 4) with the front slanted to T_2 microseconds due to the effect of leakage inductance.

To arrive at the above solution the approximate equivalent circuits of Figs. 3e and 3f were used in analyzing the L_1 and L_s transients, and the effect of the transients on each other was neglected. To illustrate the degree of accuracy obtained by this simple method, curves 5 and 6 of Fig. 4 are shown, which were obtained by rigorous solution of the exact equivalent circuit of Fig. 3c for two extreme cases (one $L_1 = M$ and the other $L_2 = M$). (See equation (**2**) in Part II.)

In T_2 microseconds the voltage of the L_s transient will rise to 95 per cent of its maximum value (E_2) while the voltage of the L_1 transient will hardly begin to fall from the same numerical value. Therefore, the first exponential term of the above equation is approximately equal to unity for at least T_2 microseconds and

$$e_2 = E_2\left(1 - e^{-\frac{Z_1 + Z_2}{L_s}t}\right)$$

This means that at $t = T_2$ $e_2 = 0.95\ E_2 = 919{,}350$

$$\left(\text{divide it by turn ratio to get actual secondary voltage}\quad \frac{919350}{5} = 183{,}830 \text{ volts}\right).$$

For the sake of simplicity this value will be considered as the practical crest of secondary voltage, and T_2 as the time of its occurrence. Fig. 5.

It is important to realize the relative duration of the L_1 and L_s transients as expressed by the ratio

$$\frac{T_1}{T_2} = \frac{L_1}{L_s} \frac{(Z_1 + Z_2)^2}{Z_1 Z_2} = \frac{1860}{6} = 310$$

In practise L_1/L_s for lightning voltages is possibly never less than five and generally is above ten. Irrespective of values of Z_1 and Z_2, $(Z_1 + Z_2)^2/Z_1 Z_2$ cannot be less than four and generally is more than ten. It follows that the L_1 transient is at least twenty times slower than the L_s transient. This justifies the above approximation of the maximum secondary voltage, and the neglecting of the effect of the above transients on each other which made possible the independent use of the simplified equivalent circuits of Figs. 3e and 3f.

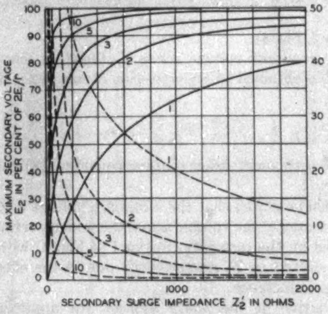

FIG. 5—EFFECT OF SECONDARY SURGE IMPEDANCE Z_2' AND TURN RATIO ON MAXIMUM VOLTAGE AND FRONT OF SECONDARY WAVE

Primary surge impedance: Z_1 = 500 ohms
Short-circuit inductance: L_s = 0.01 henrys*
Numbers on curves indicate the corresponding value of turn ratio
Solid lines = maximum voltage
Dotted lines = wave front
*(For any other value of L_s the length of the front has to be multiplied by $L_s/0.01$)

Secondary Winding Not Grounded. In the above, one terminal of the transformer secondary winding was connected to ground, and the other to a surge impedance Z_2. If both terminals were connected to identical circuits of surge impedance Z_2, then in effect the surge impedance of the secondary circuit would be doubled. Then

$$E_2 = 2E \frac{2Z_2}{Z_1 + 2Z_2} \text{ and } T_2 = \frac{3L_s}{Z_1 + 2Z_2}.$$

A voltage to ground of $\frac{E_2}{2}$ would appear on each of the two surge impedances.

Transmission of Surges Through Auto-Transformers. The relations derived above for single-phase transformers apply equally well for auto-transformers. The transmission of surges through auto-transformers was described in a previous publication.[5]

2. Finite Rectangular Primary Wave

If a rectangular primary wave has a finite length of t microseconds, the secondary wave produced is the resultant of superposition of two secondary waves, one produced by an infinite rectangular primary wave of the same polarity as the finite primary wave, and the other by an identical primary wave of opposite polarity lagging t microseconds behind the first (See Fig. 6). Since the L_1 transient is extremely slow in comparison with the length of the lightning waves found in service, it is apparent that during the short interval of t microseconds the current through L_1 will be negligible. Therefore, for the analysis of conditions found in practise, *the effect of L_1 can be completely neglected*, and the equivalent circuit of Fig. 3f is sufficiently accurate, as shown by comparison of curve 7 with 8 and 9 of Fig. 4.

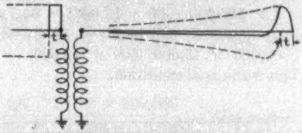

FIG. 6—SECONDARY VOLTAGE PRODUCED BY RECTANGULAR WAVE, t MICROSECONDS LONG

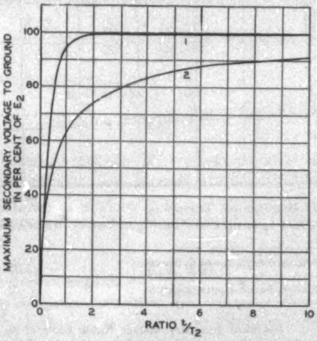

FIG. 7—EFFECT OF THE LENGTH t OF PRIMARY (APPLIED) WAVE ON THE AMPLITUDE OF THE SECONDARY WAVE

1. Finite rectangular wave applied
2. Wave with exponential tail applied

E_2 is secondary voltage produced by infinitely long rectangular wave
T_2 is secondary front produced by infinitely long rectangular wave

From curve 1, Fig. 7, it is apparent that the secondary voltage will not reach 0.95 E_2 unless the length t of the rectangular primary wave is at least equal to the length $T_2 = 3L_s/(Z_1 + Z_2)$ of the front of the secondary wave.

The fraction of this value that will be reached depends upon the ratio t/T_2 as shown in curve 1 of Fig. 7.

3. *Effect of Shape of Primary Wave*

The maximum secondary voltage produced by the primary wave having vertical front and exponential tail is shown on curve 2, Fig. 7. In this case the length t of the primary wave is measured at the level $E/2$ as is commonly done.

The steepest front T_2 of the secondary wave is produced by a rectangular primary wave. The length of secondary wave front increases as the length of the primary wave front is increased, and the two become approximately equal when the latter is more than $3T_2$.

The steepness of the secondary wave is important from the standpoint of stresses produced in rotating machines or other apparatus in the secondary circuit. The stresses, particularly between adjacent turns, are much greater for steep wave fronts. As has been shown in previous publications, these stresses depend on the ratio of T_2 to the natural period of voltage oscillations of a given piece of apparatus, or to the length T_3 of its circuit.

The voltages to ground at different points of a secondary circuit of given length depend upon the ratio T_2/T_3 as shown by Fig. 8. These curves are based on the assumption that the far end of the secondary circuit is kept at ground potential, so that secondary waves suffer negative reflection from that point. It follows from the curves that the secondary voltage cannot reach the maximum value at any point whose "distance" from the far end is less than $T_2/2$. As a result of this phenomenon, that part of Z_2 nearest the line end is subjected to high voltages more often than the rest.

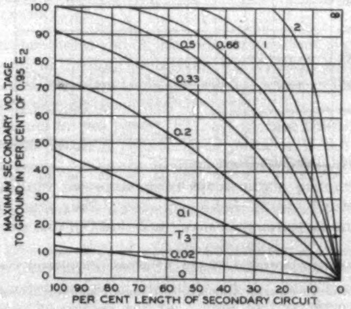

FIG. 8—EFFECT OF LENGTH OF FRONT T_2 OF SECONDARY WAVE ON MAXIMUM VOLTAGE ALONG EXTERNAL SECONDARY CIRCUIT

Total length of secondary circuit is T_3 microseconds. Far end grounded Numbers on curves indicate corresponding values of T_3/T_2

B. *Effect of Transformer Bank Connection and the Number of Phases Struck by Lightning*

Relations between the circuit constants and the crest E_2 and front T_2 of the secondary wave were established above for a single-phase transformer. Since installations of power transformers are seldom single-phase, it is important to determine the secondary voltage obtained in three-phase banks. It is apparent that the results obtained for the single-phase transformer apply directly in case both windings and generator are connected in Y with all neutrals grounded, because in such a case each phase is independent of the others. Table I shows the effect on the secondary voltage of other bank connections. For convenience of comparison the front (T_2) and crest (E_2) obtained in a single-phase transformer is taken as a reference. Figures without brackets give relative voltages and wave fronts for banks which have the same ratio of *line* voltages, while figures in brackets give the corresponding values for banks which have the same turn ratio or ratio of *phase* voltages.

TABLE I

BANK CONNECTIONS			*RELATIVE MAXIMUM SECONDARY VOLTAGE TO GROUND		AMPLITUDE FACTOR AND TIME CONSTANT (EQUATION 13-b)	
	PRIM.	SEC.	AMPLITUDE	FRONT LENGTH	A	B
1	Y⏚	Y⏚	100	100	$\frac{1}{r}\frac{q}{1+q}$	$\frac{Z_1}{L_s}(1+q)$
2	Y⏚	Y	67 (67)	100 (100)	$\frac{2}{3}\frac{1}{r}\frac{q}{1+q}$	$\frac{Z_1}{L_s}(1+q)$
3	Y	Y⏚	67 (67)	100 (100)	$\frac{2}{3}\frac{1}{r}\frac{q}{1+q}$	$\frac{Z_1}{L_s}(1+q)$
4	Y	Y	67 (67)	100 (100)	$\frac{2}{3}\frac{1}{r}\frac{q}{1+q}$	$\frac{Z_1}{L_s}(1+q)$
5	▷	▷	67 (67)	33 (33)	$\frac{2}{3}\frac{1}{r}\frac{q}{1+q}$	$3\frac{Z_1}{L_s}(1+q)$
6	▷	Y⏚	57 (100)	300 (100)	$\frac{1}{r}\frac{q/3}{1+q/3}$	$3\frac{Z_1}{L_s}(1+\frac{q}{3})$
7	▷	Y	57 (100)	300 (100)	$\frac{1}{r}\frac{q/3}{1+q/3}$	$3\frac{Z_1}{L_s}(1+\frac{q}{3})$
8	Y	▷	57 (33)	11 (33)	$\frac{1}{r}\frac{q}{1+3q}$	$\frac{Z_1}{L_s}(1+3q)$
9	Y⏚	▷	57 (33)	11 (33)	$\frac{1}{r}\frac{q}{1+3q}$	$\frac{Z_1}{L_s}(1+3q)$

*Amplitudes and lengths of fronts of the bank connections (2 to 9) are expressed in per cent of corresponding values of bank connection (1) as the base

Figures without brackets are based on equal ratio of operating line-to-line voltage

Figures in brackets are based on equal transformer turn ratio

To illustrate the simplicity of the method used in obtaining this table, the solution for secondary voltage will be analyzed for single-phase excitation of a Y-delta bank with neutral isolated and generator connected in Y.*

---

*There is considerable similarity between the method used here and that used in analysis of single-phase excitation of a three-phase system at operating frequency.

Construction of the equivalent circuit of the bank is accomplished in three steps in Fig. 9. From the relations of currents of the secondary and primary lines it is evident that in spite of the fact that each individual transformer was reduced to an equivalent 1:1 transformer the combined effect of interconnection of the three units resulted in a 1.5:1 ratio of transformation from the primary terminals (*a* to *b* and *c*) to the secondary terminals *d* to *e*). Therefore, in the final equivalent circuit, the surge impedance Z_2' is multiplied not by r^2, but by $(1.5\,r)^2$ or $2.25\,r^2$. Furthermore, since none of the secondary lines is grounded, the voltage to ground at *d* is $+\dfrac{e_2}{2}$ and at *e* is $-\dfrac{e_2}{2}$. The current in each corresponding generator phase is

$$\frac{e_2}{2 \times 2.25\,Z_2};$$

which means that in the equivalent circuit $2 \times 2.25\,Z_2$ must be substituted for the secondary surge impedance.

Since the primary current flows first through one transformer and then through the other two in multiple, the total inductance of the circuit is equal to $L_s + \dfrac{L_s}{2}$. For the same reason the combined surge impedance of phases *b* and *c* is equal to $\dfrac{Z_1}{2}$. These considerations lead to the final equivalent circuit of Fig. 9. This circuit is very similar to that of Fig. 3f and therefore we can write the following expressions:

$$E_2 = \frac{2E}{1.5\,Z_1 + 4.5\,Z_2}\,4.5\,Z_2 \times \frac{1}{1.5}$$

$$= \frac{2E}{Z_1 + 3Z_2} \times 2Z_2 \text{ volts}$$

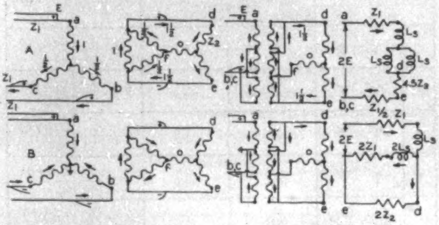

FIG. 9—DEVELOPMENT OF EQUIVALENT CIRCUITS FOR Y-DELTA TRANSFORMER BANKS CONNECTED TO A GENERATOR (BASED ON ONE-TO-ONE TRANSFORMER RATIO)

A—Primary neutral isolated
B—Primary neutral grounded

$$T_2 = \frac{3L_s}{Z_1 + 3Z_2} \text{ seconds.}$$

The voltage from one phase (*f*) of the secondary circuit to ground is zero, and from the other two (*d* and *e*) is $\pm E_2/2$.

Where $Z_1/3Z_2$ is very small, $E_2 = 2E/1.5$ and $T_2 = L_s/Z_2$. Thus the maximum possible line-to-line voltage in this case is 67 per cent and the line-to-ground voltage is 33 per cent of that for a single-phase transformer, and the front of the wave is three times as steep.

To obtain the actual secondary voltage, E_2 must be divided by the turn ratio *r*.

Since the two secondary waves are equal but opposite in polarity, the resultant voltage to ground will be zero at the point of the secondary circuit where the waves meet as at the neutral of a generator.

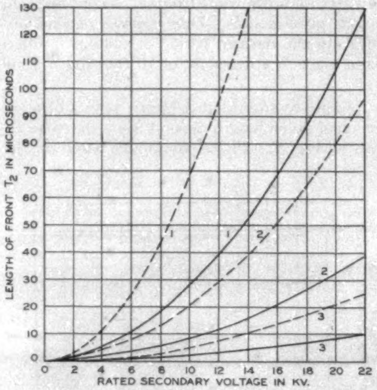

FIG. 10—LENGTH OF FRONT OF SECONDARY WAVE AS A FUNCTION OF RATED SECONDARY LINE-TO-LINE VOLTAGE

Solid curves $Z_2' = 500$ ohms. Dotted curves, $Z_2' = 200$ ohms

1. Transformer capacity 1,000 kva. per phase. Short-circuit reactance 5 per cent
2. Transformer capacity 5,000 kva. per phase. Short-circuit reactance 7.5 per cent
3. Transformer capacity 25,000 kva. per phase. Short-circuit reactance 10 per cent

Frequency 60 cycles per second. Z_2 is very large compared to Z_1
These curves apply to Y-Y connection with both neutrals grounded
For other bank connections see Table I

If identical lightning waves arrive simultaneously on two phases (*b* and *c*) with no wave on the third phase (*a*), the voltage from *b* and *c* to *a* will be the same as above (Fig. 9) and the secondary voltages therefore will be the same.

When identical lightning waves arrive simultaneously on all three phases in banks having one side connected in delta, no voltage is produced on the secondary side because the voltages in the three phases of the delta are equal and in phase.

C. *Finite Secondary Circuit*

All voltage relations established in the paper were arrived at under assumption that the time length T_3 of the secondary circuit is at least half of the total length t_2' of the secondary wave. In case the secondary circuit is shorter than that, the crest and the front of the secondary wave may be essentially different from those given above. This is caused by the phenomena of repeated reflections of the secondary wave from both ends of the circuit.

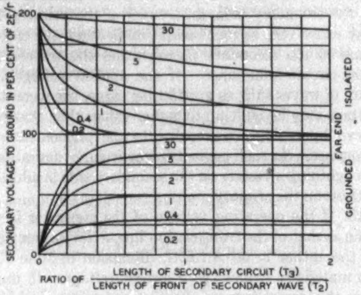

FIG. 11—SECONDARY TERMINAL VOLTAGE DUE TO REPEATED REFLECTIONS IN FINITE GROUNDED AND ISOLATED SECONDARY CIRCUITS. NUMBERS ON CURVES INDICATE CORRESPONDING VALUES OF Z_2/Z_1

In case the far end of the secondary circuit is grounded directly or through a relatively (to Z_2') low surge impedance the resultant voltage will be lower. This is the most common condition in practise because, as was explained in the paper (Fig. 9), in case the secondary external circuit is connected in delta or Y the point in that circuit, (like the neutral for example), where two secondary waves (caused by a single primary wave) meet, acts as if it were grounded (except bank connection in No. 1, Table I with primary wave on more than one phase). Fig. 11. Zone grounded.

In case the far end of the secondary circuit is open or grounded through a relatively (to Z_2') high surge impedance the voltage will be higher and its front steeper than was given previously in this paper. Such a condition is found, for example, where low voltage (secondary) buses are left connected to transformers but are disconnected from generators. Fig. 11. Zone isolated.

In case a generator is connected to transformer by means of a cable, the repeated reflections in the cable may produce voltages higher than those produced in case the generator is connected to the transformer directly. However, this voltage will be lower than that produced in the cable with generator disconnected. Fig. 12. The shape and the amplitude of these voltages can be calculated with sufficient accuracy on the assumption that the cable of surge impedance Z_2 and of a given length is equivalent to a condenser C_2 whose capacitance is equal to that of the cable. (Fig. 12.)

CONCLUSIONS

The voltage on the secondary terminals of a transformer produced by an impact of a lightning wave on the primary side consists of four components. The magnitude of the voltage due to the fourth component generally is much higher than that produced by the second and third components and may be exceeded only by that produced by the first, under certain special conditions.

When the surge impedance Z_2' of the external secondary circuit is very high or the circuit is short, amplitudes of each of the four components may be dangerously high.

The voltages due to the first three components depend on the relative position and distribution of windings and of the core, and may be essentially different in transformers of identical operating characteristics, like short-circuit reactance, kva. rating, etc., but of different types of design.

The fourth component, the electromagnetic, depends only on the short-circuit reactance of a transformer and is the same for transformers having the same reactance (in henrys) and the same turn ratio no matter how different may be their design features.

For the above reasons, in a general discussion of characteristics of lightning voltages transmitted to the secondary network, little can be said about the first three components that would be applicable to all transformers, particularly because the essential design features of a given transformer are generally known only to its manufacturer. On the other hand, the value of short-circuit reactance and of turn ratio of transformers is generally known and therefore very definite and specific conclusions can be drawn in regard to the voltage produced by the fourth component.

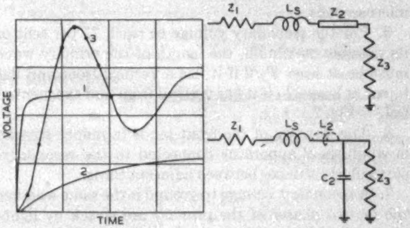

FIG. 12—EFFECT OF CABLE AND CAPACITOR ON SECONDARY VOLTAGE TO GROUND (CALCULATED)

1. Generator (Z_3) connected directly. $Z_2 = 0$
2. Generator (Z_3) connected through cable (Z_2)
   Repeated reflections are neglected
3. Generator (Z_3) connected through cable (Z_2)
   Repeated reflections are taken into account. Dots indicate points calculated by method of repeated reflections. Curve is calculated with total capacitance (C_2) and total inductance (L_2) of cable substituted for its surge-impedance (Z_2)

The following conclusions may be drawn concerning voltages produced on secondary circuits by the *electromagnetic components.*

1. The effect of a transformer on lightning voltages, transformed electromagnetically to the secondary network, is practically the same as that of an inductance equal to the short-circuit inductance of the transformer, connected between the primary and secondary lines (in the equivalent circuit reduced to 1:1 ratio). Figs. 3 and 4.

2. The ratio of crests of primary and secondary voltage is practically equal to the ratio of turns of the respective windings, where surge impedance of primary circuit is negligible in comparison with the effective surge impedance ($Z_2 = Z_2' r^2$) of the secondary circuit, as often is the case. (Fig. 5.)

3. On overhead transmission lines the amplitude of a relatively long (20 microseconds or more) traveling wave may be six times the system operating voltage (crest). It follows that such a wave may produce a secondary voltage of 3.4 to 6 times the secondary operating voltage, depending upon the transformer bank connection used. (Table I)

4. Although the front of an incident traveling wave may be vertical, the front (T_2) of the secondary wave is always slanted due to the effect of short-circuit inductance of the transformer. The front (T_2) is shortest where transformers of large kva. capacity and of relatively low voltage and reactance are connected to circuits of high-surge impedance, and is longest where the opposite is the case. In general the length of the front ranges from a few to a hundred microseconds (Fig. 10), but in exceptional cases may reach several thousand microseconds.

5. For the secondary voltage to reach 75 per cent of its possible maximum, the length of the primary wave must be at least $T_2/2$ if it has a vertical front and flat top or at least $2T_2$ if it has vertical front and exponential tail. (Fig. 7.)

6. The slanting of the front tends to reduce stresses in windings of apparatus connected to the secondary, particularly stresses between adjacent turns.

7. A secondary voltage to ground is the same whether one or two phases of the primary are struck by lightning. If either primary or secondary, or both, are connected in delta, then, when all three primary phases are struck by equal traveling waves, no secondary voltages will be produced.

8. With the exception of the Y-Y bank with both neutrals grounded, all three-phase bank connections produce zero lightning voltage at the isolated neutral of generators connected in Y.

9. A few hundred feet of metal-clad cable, connected between a transformer and generator, may materially slope the front of a secondary voltage wave, but substantially increase the amplitude if the primary wave is sufficiently long. The same is true of relatively small capacitances connected from the generator terminals to ground. (Fig. 12) (See Part II)

10. A neutral grounding resistance on the primary side tends to reduce the amplitude and shorten the front of the secondary wave. A reactance tends to increase the length of the front and thereby reduce the maximum amplitude produced by relatively short waves. In practise, the effect of the resistance will be small, while that of the reactor may be appreciable.

11. Protective gaps and lightning arresters are more effective in reducing secondary voltage when connected on the primary side. When connected on the secondary side, the sudden arcing of the gap or of the arrester may cause considerable stresses between turns of connected apparatus. This is not true in case the arrester has the proper negative volt-ampere characteristics.

12. Where capacitances or metal-clad cables are used on the secondary side, an arcover of the primary line may cause very serious oscillation between the capacitance of the secondary network and the transformer short-circuit inductance. If the applied voltage is a train of waves such as a switching surge, the secondary voltage may be built up to higher values than that produced by a single wave, due to the phenomenon of resonance. In such cases it is particularly desirable to use lightning arresters on the secondary side in addition to those on the primary.

13. If the operating voltage of the generator is the same as that of the transmission line, a device described by the author in an A.I.E.E. discussion in June 1930 can materially reduce the transient voltage. In many cases this device is more effective and economical than a 1:1 delta Y transformer bank that reduces voltages to 57 per cent (or less) of the value of the incoming wave.[6]

14. Where the "time length" (T_3) of a secondary circuit is short, in comparison with the length of the secondary wave, voltages in excess of that mentioned in conclusion 2 may result (Fig. 11). For this reason, particularly high secondary voltages may be expected on low-voltage buses disconnected from the apparatus and the network.

15. The above analysis was made for a transformer. It is obvious, however, that the same formulas apply also to the analysis of a rotating machine and of an induction regulator due to the presence of "transformer action" between windings.

Part II

When a lightning wave strikes the terminal of the primary winding of a transformer, four distinct phenomena contribute to the transient in the secondary winding. These are discussed in the first part of the paper. The electromagnetic transfer of the lightning wave has predominating influence on the secondary transient as far as secondary terminal voltages are concerned, provided lines, cables or generators of relatively low surge impedance are connected to the secondary winding.

A. SINGLE-PHASE TRANSFORMER WITH GROUNDED NEUTRAL

Calculations for single-phase connection are chosen to derive simple equations for the electromagnetic transformation of lightning waves in inductive windings. They can be applied directly for Y-Y connected transformer banks with both neutrals grounded, and are the basis for solution of other transformer connections.

Fig. 3a shows the diagrammatic sketch of a two-winding transformer, with primary and secondary transmission lines. This can be simplified to Fig. 3b, where the surge impedances are reduced to resistances (provided the lines are long) and the applied voltage has twice the amplitude of the traveling wave of Fig. 3a. The internal resistances of the windings are in general too small to affect the result and therefore can be neglected. If in any case it should appear necessary to take these resistances into account, they may be inserted in series with the corresponding surge impedances of the lines. The fundamental equations for voltages and currents in operational form are:

$$2E = (Z_1' + pL_1')\, i_1 \pm pMi_2'$$
$$0 = (Z_2' + pL_2')\, i_2 \pm pMi_1'$$

where $p = \dfrac{d}{dt}$ is Heaviside's operator. Solving these two simultaneous equations for i_2 gives

$$i_2 = \mp \frac{2E\,M'}{L_1'L_2' - M'_2}\,\frac{p}{p^2 + 2\alpha' p + \omega_o'^2};$$

$$e_2 = i_2 Z_2' = \mp \frac{2E\,M'Z_2'}{L_1'L_2' - M'^2}\,\frac{p}{p^2 + 2\alpha' p + \omega_o'^2}$$

The solution[8] of this equation is

$$e_2 = \mp \frac{2E\,M'Z'_2}{L_1'L_2' - M'^2}\,\frac{\epsilon^{-m't} - \epsilon^{-n't}}{n' - m'}$$

$$= \mp \frac{2E\,M'Z_2'}{\sqrt{(L_1'Z_2' - L_2'Z_1')^2 + 4Z_1'Z_2'M'^2}}\,(\epsilon^{-m't} - \epsilon^{-n't}) \qquad \text{(1a)}$$

where

$$n' = \frac{L_2'Z_1' + L_1'Z_2' + \sqrt{(L_2'Z_1' - L_1'Z_2')^2 + 4Z_1'Z_2'M'^2}}{2\,(L_1'L_2' - M'^2)};$$

$$m' = \frac{L_2'Z_1' + L_1'Z_2' - \sqrt{(L_2'Z_1' - L_1'Z_2')^2 + 4Z_1'Z_2'M'^2}}{2\,(L_1'L_2' - M'^2)} \qquad \text{(1b)}$$

The same solution has been published by various authors. In a practical case the sign should be determined by the polarity of the transformer. It will be assumed positive in the rest of the paper. The constants used in the equation are all physical constants, which should be calculated from the physical configuration of the coils and transmission lines. The equation can be rewritten using constants which are converted to the primary side (or secondary) as for the equivalent transformer circuit (Fig. 3c).

$Z_1 = Z_1'$; $L_1 = L_1'$; $M = rM'$; $L_2 = r^2L_2'$; $Z_2 = r^2Z_2'$

r = ratio of primary turns to secondary turns.

Then

$$e_2 = \frac{2E}{r}\,\frac{Z_2M}{\sqrt{(L_1Z_2 - L_2Z_1)^2 + 4Z_1Z_2M^2}}\,(\epsilon^{-mt} - \epsilon^{-nt}) \qquad \text{(2)}$$

$$e_2\, max = 2E\,A\,C \qquad \text{(3)}$$

where amplitude factor

$$A = \frac{1}{r}\,\frac{Z_2M}{\sqrt{(L_1Z_2 - L_2Z_1)^2 + 4Z_1Z_2M^2}} \qquad \text{(4)}$$

and crest factor C is the maximum value of $(\epsilon^{-mt} - \epsilon^{-nt})$ as t is varied. The expressions for n and m are identical to those for n' and m' using constants of the equivalent circuit in place of the physical constants. Values of Z_1 and Z_2, representing surge impedances of transmission lines, cables and generators can be obtained quite readily, while the evaluation of L_1, L_2 and M requires involved calculations or tests. In any given transformer the values of L_1, L_2 and M are not constant due to saturation and skin effect in the core. Fortunately results within engineering accuracy can be obtained although the absolute values of inductances are not known. The following transformation will show that a wide variation in absolute values of inductance produces only a small variation in the amplitude of the secondary wave and therefore a simplified equation can be used.

The amplitude factor (4) can be rewritten as

$$A = \frac{1}{r}\,\frac{1}{\sqrt{\left(\frac{L_1}{M} - \frac{Z_1}{Z_2}\,\frac{L_2}{M}\right)^2 + 4\,\frac{Z_1}{Z_2}}}$$

and substituting:

$c = \dfrac{M}{L_1}$; $d = \dfrac{M}{L_2}$; $q = \dfrac{Z_2}{Z_1}$ = effective ratio of secondary to primary surge impedance

$$q = r^2 s;\ s = \frac{Z_2'}{Z_1'}$$

and

$L_s = \dfrac{L_1L_2 - M^2}{L_2} \cong L_1 + L_2 - 2M$ = Short-circuit inductance in henrys.

$$A = \frac{1}{r}\,\frac{q}{\sqrt{\left(\frac{q}{c} - \frac{1}{d}\right)^2 + 4q}} \qquad \text{(5)}$$

The crest factor is a function of n/m

$$n = \frac{Z_1}{2L_s}\left(1 + \frac{dq}{c} + \sqrt{\left(1 + \frac{dq}{c}\right)^2 - 4\,\frac{L_s}{M}\,dq}\right)$$

$$m = \frac{Z_1}{2L_s}\left(1 + \frac{dq}{c} - \sqrt{\left(1 + \frac{dq}{c}\right)^2 - 4\,\frac{L_s}{M}\,dq}\right) \qquad \text{(6)}$$

Approximate Solution. In concentric construction either L_1 or L_2 is approximately equal to M, depending on the position of the coils with respect to each other and the core, and therefore either c or d will be approximately equal to unity. In interleaved construction the value of L_1 is approximately equal to L_2 and therefore c is approximately equal to d. In the following tables the variation of the maximum secondary voltage is given for two conditions, *i.e.*, $M/L_1 = 1$ and $M/L_2 = 1$. The short-circuit inductance L_s remains constant at 0.2 henrys, while it is arbitrarily assumed that the primary or secondary inductances change from 1 henry (air-core) to 100 henrys (iron-core). Amplitude factors, crest factors and maximum secondary voltages obtained with air-core inductance are expressed in per cent of the corresponding values obtained with iron-core inductance

Constants	L_1 henrys	L_2 henrys	M henrys	$C = \frac{M}{L_1}$	$d = \frac{M}{L_2}$	$\frac{L_s}{M}$
Iron-core (i)	100	M	99.8	0.998	1	0.002
Air-core (a)	1	M	0.8	0.8	1	0.25
Iron-core (i)	M	100	99.8	1	0.998	0.002
Air-core (a)	M	1	0.8	1	0.8	0.25

$q = \frac{Z_2}{Z_1}$	$\frac{A(a)}{A(i)} \times 100$	$\frac{C(a)}{C(i)}$	$\frac{e_2 \max (a)}{e_2 \max (i)} \times 100$	
1	99.4	78.8	78.4	$L_2 = M$
100	80.3	99.5	80.0	
1	99.2	75.5	74.8	$L_1 = M$
100	98.3	98.0	97.3	

This table shows that the maximum secondary voltages for air-core are 75 to 97 per cent of those for iron-core or in other words, the secondary voltage varies not over 25 per cent even for the extreme conditions assumed here. In nearly all practical cases L_s/M will be smaller than 0.1, which will decrease the variation of maximum voltage to 10 per cent or less. Considering the narrow range between air-core and iron-core values of maximum secondary voltages, it is justifiable to substitute $c = 1$ in equations (**5**) and (**6**). The equation for secondary voltage then is reduced to a very simple form (exponent m becomes so small compared to n that ϵ^{-mt} equals 1 for all practical purposes).

$$e_2 = 2E \, \frac{1}{r} \, \frac{q}{q+1} \left(1 - \epsilon^{-\frac{Z_1}{L_s}(1+q)t}\right) \tag{7}$$

This equation gives a good approximation for the front and the maximum amplitude of the secondary wave and e_2 is reduced to a function of only the effective ratio of secondary to primary surge impedances, the primary surge impedance and the short-circuit inductance of the transformer. In the case of infinitely long wave this equation would obviously give incorrect results for the tail of the secondary waves. However, for waves of the length found in practise, good approximate results are obtained when the approximate equations (**8b**) and (**9b**) are used (Fig. 4). The circuit representing equation (**7**) is shown in Fig. 3f and consists of two transmission lines joined by the short-circuit inductance of the transformer.

Finite Wave. Equations developed so far represent the secondary wave when the lightning wave has rectangular front and infinitely long tail. By means of Duhamel's theorem or Heaviside's shifting theorem[8] equations can be obtained for the secondary voltage, when the applied wave is not rectangular. Equations (**8a**) and (**9a**), give voltages for the circuits of Fig. 3c and (**8b**) and (**9b**) for circuit Fig. 3f.

If the applied wave at the terminals of the equivalent circuits

$$e = 2E\,(\epsilon^{-at} - \epsilon^{-bt})^*$$

then

$$e_2 = 2E\,A \left\{ \left(\frac{a}{m-a} - \frac{b}{m-b}\right)\epsilon^{-mt} - \left(\frac{a}{n-a} - \frac{b}{n-b}\right)\epsilon^{-nt} + \left(\frac{a}{n-a} - \frac{a}{m-a}\right)\epsilon^{-at} - \left(\frac{b}{n-b} - \frac{b}{m-b}\right)\epsilon^{-bt} \right\} \tag{8a}$$

$$e_2 = 2E\,A \left\{ \left(\frac{n}{n-a}\right)\epsilon^{-at} - \frac{n}{n-b}\,\epsilon^{-bt} - \left(\frac{a}{n-a} - \frac{b}{n-b}\right)\epsilon^{-nt} \right\} \tag{8b}$$

or if the applied wave is

$$e = 2E\,(\epsilon^{-at})^*$$

$$e_2 = 2E\,A \left\{ \left(\frac{a}{n-a} - \frac{a}{m-a}\right)\epsilon^{-at} + \frac{m}{m-a}\,\epsilon^{-mt} - \frac{n}{n-a}\,\epsilon^{-nt} \right) \right\} \tag{9a}$$

or $$e_2 = 2E\,A_1\,(\epsilon^{-at} - \epsilon^{-nt}) \tag{9b}$$

where $$A_1 = \frac{n}{n-a}\,A = \frac{n}{n-a}\,\frac{1}{r}\,\frac{q}{q+1}$$

B. THREE-PHASE BANKS

In the previous discussion it is shown that the transformer circuit of Fig. 3a can be simplified to that of Fig. 3f without appreciable error. The same principle can be applied to three-phase connections of transformers. Fig. 9 shows the equivalent circuits for Y-delta connected banks. Only the solution for the condition of grounded primary neutral is discussed here.

The general solution for the voltage e_b across surge impedance Z_b is

$$e_b = 2E\,\frac{1}{r} \left\{ \frac{Z_b Z_c}{Z_a Z_b + Z_a Z_c + Z_b Z_c} \left(1 - \frac{n\epsilon^{-mt} - m\epsilon^{-nt}}{2\omega}\right) + \frac{Z_b}{Z_a}\,\frac{\epsilon^{-mt} - \epsilon^{-nt}}{2\omega} \right\} \tag{10}$$

---

*These applied waves are equivalent to traveling waves of $e = E\,(\epsilon^{-at} - \epsilon^{-bt})$ and $e = E\,\epsilon^{-at}$ respectively.

and the general solution for voltage e_c is

$$e_c = 2E\frac{1}{r}\,\frac{Z_bZ_c}{Z_b+Z_aZ_c+Z_bZ_c}\left\{1-\frac{1}{2\omega}(n\epsilon^{-mt}-m\epsilon^{-nt})\right\} \tag{11}$$

where $m = \alpha - \omega; \quad n = \alpha + \omega$

$$\alpha = \frac{1}{2}\,\frac{L_a(Z_b + Z_c) + L_b(Z_a + Z_b)}{L_aL_b};$$

$$\omega_o^2 = \frac{Z_aZ_b + Z_aZ_c + Z_bZ_c}{L_aL_b}; \omega = \sqrt{\alpha^2 - \omega_o^2}$$

By inspection the following relations will be found (all constants are transferred to the primary phase on which the lightning wave travels).

$Z_a = Z_1; Z_b = 2r^2Z_2' = 2r^2sZ_1 = 2qZ_1; Z_c = 2Z_1$

$L_a = L_s$ = short-circuit inductance of one transformer.

$L_c = 2\,L_s$

Substitution of these values in equation (**10**) gives

$$e_b = 2E\,\frac{1}{r}\,\frac{2q}{1+3q}\,(1 - \epsilon^{-nt}) \tag{12}$$

The value of n is given in Table I.[9] Keeping in mind that e_b is the voltage across the secondary winding and that Z_b represents the surge impedance of two secondary lines in series it will be found that the waves traveling on two secondary lines (the voltage at the third secondary line is zero) have an amplitude of one-half the value of e_b and are of opposite polarity.

$$e_2 = \pm\,2E\,\frac{1}{r}\,\frac{q}{1+3q}\,(1 - \epsilon^{-nt}) \tag{13a}$$

or $e_2 = \pm\,2E\,A\,(1 - \epsilon^{-nt})$ (**13b**)

Due to this fact the voltage at the generator neutral, where the two waves meet will be zero. The same reasoning can be applied to other bank connections, with the exception of the Y-Y bank with both neutrals grounded. Similarly the super-position of positive and negative waves in the phases of a delta-connected generator will cause a great reduction of voltage, where the secondary waves meet.

Equation (**13b**) is the solution for secondary voltages when identical lightning waves come in on one line only or on two lines simultaneously. If identical lightning waves come in on all three primary lines simultaneously no voltages will appear on the secondary lines. The same is true for all other bank connections of Table I with the exception of Y-Y bank with both neutrals grounded. Equation (**13b**) applies equally well for all bank connections, when tabulated values of amplitude factors (A) and time constants 1/11 are substituted.

Equation (**13b**) has the same form as (**7**) for single-phase connection (or Y-Y bank with both neutrals grounded) and equations (**8**) and (**9**) for waves with finite front and tail apply equally well requiring only the substitution of the correct amplitude factors and time constants.

The voltage on either of the two unexcited high-voltage lines becomes:

$$e_c = 2E\left(\frac{q}{1+3q} - \frac{1}{3}\,\epsilon^{-mt} + \frac{1}{3}\,\frac{1}{1+3q}\,\epsilon^{-nt}\right);$$

$$m = \frac{Z_1}{L_s} \qquad n = \frac{Z_1}{L_s}\,(1+3q) \tag{14}$$

For an infinite rectangular wave the final value of e_c is r times as great as that of the secondary wave. The fronts of the waves on the high-voltage lines are, however, in general much slower than the fronts of the secondary waves. The maximum value of the wave is at the most 1/3 that of the lightning wave.

C. Repeated Reflection

In drawing the simplified circuit of Fig. 3b it was assumed that primary and secondary lines are very long. This assumption made possible the change from surge impedance to pure resistance. Although this assumption may be justified for the primary lines, it would give wrong results when secondary lines consist of short cables or overhead lines between the secondary of the transformer and the generator terminal or the finite length of generator windings. In such cases the replacement of the surge impedance is valid only until the wave returns to the transformer terminal after being reflected from the far end of the secondary line. From that instant on the returned wave and its reflection on the transformer terminals should be added to the initial secondary wave (see Fig. 12). If the reflection operator on the far end of the line is R_g and the reflection operator on the transformer terminal is R_T, then the resulting secondary voltage for single-phase transformation due to reflection can be written as:

$$e_{2res} = e_2 + (R_ge_2 + R_TR_ge_2)_{(t-2T)} + (R_g^2R_Te_2 + R_g^2R_T^2e_2)_{(t-4T)} + (R_g^3R_T^2e_2 + R_g^3R_T^3e_2)_{(t-6T)} + \ldots \tag{15}$$

where $2T$ indicates the time interval during which the original wave travels twice the length of the secondary line, taking into account the velocity of propagation, which is different for transmission lines (1,000 ft. per microsecond) cables (500 ft. per microsecond) and generators (100 ft. per microsecond). The subscript $(t - 2T)$ indicates that the two waves in the brackets have to be added to the previous wave at time $t = 2T$. Suppose the secondary line or cable with surge impedance Z_2 is starting at the far end to a generator with a surge impedance of Z_3 ohms then

$$R_g = \frac{Z_3 - Z_2}{Z_3 + Z_2}$$

In Y-connected generators, Z_3 is the surge impedance of one phase, in delta-connected generators Z_3 = one-half the surge impedance of one phase.

For the simplified circuit of Fig. 3f the reflection factor R_T at the transformer terminals becomes

$$R_{\mathrm{T}} = \frac{Z(p) - Z_2}{Z(p) + Z_2} = \frac{pL_s + Z_1 - Z_2}{pL_s + Z_1 + Z_2}$$

$$= \frac{p + \dfrac{Z_1 - Z_2}{L_s}}{p + \dfrac{Z_1 + Z_2}{L_s}} = \frac{p + \beta}{p + \alpha}$$

The solution for R_{T} for an infinite long wave with rectangular front is

$$R_{\mathrm{T}} = \frac{\beta}{\alpha} + \epsilon^{-\alpha t}\left(1 - \frac{\beta}{\alpha}\right)$$

The applied wave in this case is, however, the original secondary wave (equation (7)) reflected at the generator end and equals

$$R_g e_2 = 2E\,\frac{Z_3 - Z_2}{Z_3 + Z_2}\,A\,(1 - \epsilon^{-\alpha t})$$

Using the Heaviside shifting theorem or Duhamel's theorem the reflected wave resulting when $R_g e_2$ is applied becomes

$$R_g R_{\mathrm{T}} e_2 = 2E\,\frac{Z_3 - Z_2}{Z_3 + Z_2}\,A\left\{\frac{\beta}{\alpha} - \epsilon^{-\alpha t}\left[\alpha t\left(\frac{\beta}{\alpha} - 1\right) + \frac{\beta}{\alpha}\right]\right\}$$

This wave travels out on the line, is reflected at the generator, and a wave $R_g^2 R_{\mathrm{T}} e_2$ returns. $R_g^2 R_{\mathrm{T}} e_2$ is the wave to be used as applied wave in this case.

$$R_g^2 R_{\mathrm{T}} e_2 = 2E\left(\frac{Z_3 - Z_2}{Z_3 + Z_2}\right)^2 A\left\{\left(\frac{\beta}{\alpha}\right) - \epsilon^{-\alpha t}\left[(\alpha t)\left(\frac{\beta}{\alpha} - 1\right) + \frac{\beta}{\alpha}\right]\right\}$$

and the reflected voltage at the transformer becomes

$$R_g^2 R_{\mathrm{T}}^2 e_2 = 2E\left(\frac{Z_3 - Z_2}{Z_3 + Z_2}\right)^2 A\left\{\left(\frac{\beta}{\alpha}\right)^2 - \frac{\epsilon^{-\alpha t}}{2}\left[(\alpha t)^2\left(\frac{\beta}{\alpha} - 1\right)^2 + 2\alpha t\left\{\left(\frac{\beta}{\alpha}\right)^2 - 1\right\} + 2\left(\frac{\beta}{\alpha}\right)^2\right]\right\}$$

or in general the nth reflection at the transformer terminal becomes

$$R_g^n R_{\mathrm{T}}^n e_2 = 2E\left(\frac{Z_3 - Z_2}{Z_3 + Z_2}\right)^n A\left\{\frac{\beta^n}{\alpha^n} - \epsilon^{-\alpha t}\left[\frac{(\beta t)^n}{\underline{\lfloor n}} + \sum_0^n{}^k\left\{\left(\frac{\beta}{\alpha}\right)^k \frac{(\beta t)^{n-k}}{\underline{\lfloor n-k}} - \frac{\underline{\lfloor n}}{\underline{\lfloor n-k}}\,\frac{\beta^{n-k}}{\underline{\lfloor k}}\right.\right.\right.$$

$$\left.\left.\left.\sum_0^{k-1}{}^\gamma\,\frac{\alpha^{k-\gamma}}{\underline{\lfloor n-\gamma}}\,\frac{t^{n-\gamma}}{\underline{\lfloor k-1-\gamma}}\,\frac{\underline{\lfloor k-1}}{\underline{\lfloor \gamma}}(-1)^{k-1-\gamma}\right)\right\}\right]\right\} \quad (16)$$

or if the applied wave is of the form $e = 2E\,\epsilon^{-at}$

$$R_g^n R_{\mathrm{T}}^n e_2 = 2E\left(\frac{Z_3 - Z_2}{Z_2 + Z_3}\right)^n A_1\left\{\left(\frac{\beta - a}{\alpha - a}\right)^n \epsilon^{-at}\right.$$

$$- \epsilon^{-\alpha t}\left[\frac{\beta - a}{\alpha - a}\,\frac{((\beta - a)t)^{n-1}}{\underline{\lfloor n-1}} - \frac{(-(\alpha - a)\,t)^{n-1}}{\underline{\lfloor n-1}}\right.$$

$$+ \frac{(\beta t)^n + (-\alpha t)^n}{\underline{\lfloor n}} + 1$$

$$+ \sum_1^{n-1}{}^k\left(\frac{\beta - a}{\alpha - a}\,\frac{((\beta - a)t)^{n-1}}{\underline{\lfloor n-1-k}}\,\frac{1}{((\alpha - a)t)^k}\right.$$

$$- \frac{(-(\alpha - a)t)^{n-1-k}}{\underline{\lfloor n-1-k}\;\underline{\lfloor k}}\,\frac{\underline{\lfloor n-1}}{\underline{\lfloor n-1-k}}$$

$$+ \frac{\underline{\lfloor n}}{\underline{\lfloor n-k}}\,\frac{(-\alpha t)^{n-k}}{\underline{\lfloor n-k}\;\underline{\lfloor k}} - \frac{\underline{\lfloor n}}{\underline{\lfloor n-k}}\,\frac{(\beta - a)^{n-k}}{\underline{\lfloor k}}$$

$$\sum_0^{k-1}{}^\gamma\left\{\frac{(-(\alpha - a)^{k-1-\gamma}}{\underline{\lfloor n-1-\gamma}}\,\frac{t^{n-1-\gamma}}{\underline{\lfloor k-1-\gamma}}\,\frac{\underline{\lfloor k-1}}{\underline{\lfloor \gamma}}\right\}$$

$$+ \frac{\underline{\lfloor n}}{\underline{\lfloor n-k}}\,\beta^{n-k}\sum$$

$$\left.\left.\left.\sum_0^k{}^\gamma\left\{\frac{(-\alpha)^{k-\gamma}}{\underline{\lfloor n-\gamma}}\,\frac{t^{n-\gamma}}{\underline{\lfloor k-\gamma}}\,\frac{\;}{\underline{\lfloor \gamma}}\right\}\right)\right]\right\} \quad (17)$$

$$A_1 = A\,\frac{\alpha}{\alpha - a};\ \beta = \frac{Z_1 - Z_2}{L_s} = \frac{Z_1}{L_s}(1 - q);$$

$$\alpha = \frac{Z_1 + Z_2}{L_s} = (1 + q)\,\frac{Z_1}{L_s}$$

a = exponent of the applied wave.

Equations (16) and (17) can be used for single-phase connections and also for those bank connections, which can be represented by equivalent circuits similar to Fig. 9A.

The equation for equivalent circuit of Fig. 9B for rectangular primary wave when a short cable or line (Z_2) is placed between the generator (Z_3) and the secondary winding of the transformer is

$$R_g^n R_{\mathrm{T}}^n e_2 = 2E\left(\frac{Z_3 - Z_2}{Z_3 + Z_2}\right)^n A\left[D^n(1 - \epsilon^{-\alpha t})\right.$$

$$+ \alpha D^n\,\epsilon^{-\alpha t}\sum_1^n{}^k\left(\frac{\underline{\lfloor n}}{\underline{\lfloor n-k}}\left(\frac{B}{D}\right)^k \frac{1}{\underline{\lfloor k}}\sum_0^{k-1}{}^\gamma\right\{$$

$$\left.\left.\sum_0^{k-1}{}^\gamma\left\{\frac{(-\alpha)^{k-1-\gamma}}{\underline{\lfloor \gamma}}\,\frac{t^{k-\gamma}}{\underline{\lfloor k-\gamma}}\,\frac{\underline{\lfloor k-1}}{\underline{\lfloor k-1-\gamma}}\right\}\right)\right] \quad (18)$$

$$D = \frac{1-3q}{1+3q}; B = \frac{6q}{1+3q}; \alpha = \frac{Z_1}{L_s}(1+3q); q = \frac{Z_2}{Z_1}.$$

Simplified Solution. A simpler method of solution for secondary voltages due to repeated reflections consists in the replacement of the surge impedance of the secondary line or cable by their capacitance to ground (Fig. 12). In case the inductance of the line or cable is comparable to the short-circuit inductance of the transformer it should be added to L_s. The solution for single-phase transformation and all bank-connections, which can be represented by an equivalent circuit similar to Fig. 3a, is for

$e = E$ (traveling wave)

$$e_2 = 2E\,A\left\{1 - \frac{\omega_o}{\omega}\epsilon^{-\alpha t}\sin\left(\omega t + \tan^{-1}\frac{\omega}{\alpha}\right)\right\}$$

$$\text{if } \omega_o^2 > \alpha^2 \qquad \textbf{(19a)}$$

$$e_2\,max = 2E\,A\left(1 + \epsilon^{-\frac{\alpha}{\omega}\pi}\right)$$

since $t_1 = \dfrac{\pi}{\omega}$ is the time at which the maximum occurs.

$$e_2 = 2E\,A\left\{1 - \frac{1}{n-m}(n\epsilon^{-mt} - m\epsilon^{-nt})\right\} \text{ for } \alpha^2 > \omega_o^2$$

$$\textbf{(19b)}$$

for $e = E\,\epsilon^{-at}$ (traveling wave)

$$e_2 = 2E\,A\left\{\frac{\omega_o^2}{(\alpha-a)^2+\omega^2}\left[\epsilon^{-at}\right.\right.$$

$$\left.\left. - \frac{\sqrt{(\alpha-a)^2+\omega^2}}{\omega}\epsilon^{-\alpha t}\sin\left(\omega t + \tan^{-1}\frac{\omega}{\alpha-a}\right)\right]\right\}$$

$$\text{if } \omega_o^2 > \alpha^2 \qquad \textbf{(20a)}$$

$$e_2 = 2E\,A\frac{\omega_o^2}{(\alpha-a)^2+\omega_1^2}\left\{\epsilon^{-at}\right.$$

$$\left. - \frac{(a-m)\,\epsilon^{-nt} - (a-n)\,\epsilon^{-mt}}{n-m}\right\}$$

$$\text{if } \alpha^2 > \omega_o^2 \qquad \textbf{(20b)}$$

where

$$\alpha = \frac{1}{2}\left(\frac{Z_1}{L_s} + \frac{1}{C_2 Z_3}\right); \omega_o^2 = \frac{Z_1 + Z_3}{Z_3}\;\frac{1}{L_s C_2};$$

$$\omega = \sqrt{\omega_o^2 - \alpha^2}$$

$$n = \alpha + \omega_1; m = \alpha - \omega_1; \omega_1 = \sqrt{\alpha^2 - \omega_o^2}$$

It should be noted that in this case $q = r^2 \dfrac{Z_3'}{Z_1'}$.

Solution by means of equations (**19**) and (**20**) shows a good agreement, with the solution obtained by method of repeated reflections when the front of the secondary wave is longer than twice the length of the line or cable. If the front of the secondary wave is shorter than double the length of the line or cable only approximate results are obtained since in such a case the repeated application of steep fronts is neglected. Equations (**19**) and (**20**) can also be used, to calculate the voltage rise at the generator terminals, when a protective capacitor is used.

CONCLUSIONS

1. For the purpose of calculation of the electromagnetic transformation of lightning waves, the complicated transformer circuit can be replaced by an inductance equivalent to the short-circuit reactance of the transformer. The results obtained are in nearly all practical cases within 10 per cent of the real values.

2. Similarly bank connections can be reduced to simple equivalent circuits, which allow ready calculation of secondary voltages in networks.

3. Repeated reflections on short secondary lines or cables which are connected to generators or transformers on the far end may materially increase the amplitude of the secondary voltage over that obtained if the generator had been connected directly although the rate of rise of secondary voltage may be lower. The same is true, if small protective capacitors are used.

ACKNOWLEDGMENT

The authors gratefully acknowledge valuable suggestions and assistance given by Mr. W. A. McMorris of the Power Transformer Department during the preparation of this paper.

Discussion

F. W. Peek, Jr.: The paper gives a practical method of determining the voltages that pass through the low side when the high side of a transformer is subjected to lightning. By means of this method the stresses on generators and other low side apparatus can be predetermined and adequate protective measures taken. This paper is one of a pioneer series by Mr. Palueff and his associates (Messrs. Weed, Blume, Boyajian, Brand and others) that has placed the subject of transients in transformer windings upon a scientific and engineering basis. The results of this study have been more than a theoretical treatment. From it came the now well-known non-resonating transformer in which the voltage stresses in any part of the winding and through the insulation structure are always uniform and relatively the same whether the applied voltage is at operating frequency, lightning impulses or high frequency. This ideal transformer thus has the same relative strength under all types of voltages. The designer knows just how much insulation to place at any particular part. He also knows that, whatever the type of test—60 cycles or lightning—the stresses are the same. Thus for this transformer the usual A.I.E.E. acceptance tests are equivalent to lightning tests.

I bring up the matter of testing because I feel that in view of the new knowledge resulting from this series of papers the commercial testing of transformers at operating frequencies should be reviewed by the Machinery Committee of the Institute and recommendations made for revision, if it seems advisable. A method of determining the corona point in oil in the 60-cycle test should be considered for reasons that I will bring out later. *I further recommend that this same committee set up methods, waves, etc., for making a lightning test on transformers* if such a test seems desirable. I suggest an A.I.E.E. committee for this work because of the highly technical problems involved. High-voltage testing is rather expensive and, since much depends upon it, should be made as effective as possible. I do not hesitate to recommend the consideration of commercial lightning testing after years of experience with such testing on complete transformers for the purpose of design. This testing was necessary because we have been building transformers lightning proof for a number of years. Someone has referred to impulse tests made in Europe. These tests are of such a mild value as to be useless.

One of the most important problems in establishing lightning tests is to devise means for detecting incipient turn-to-turn, coil-to-coil, or other failures. This is so because the operator must feel assured beyond any reasonable doubt that the transformer is as good after the test as it was before the test. Follow-up 60-cycle tests will not necessarily detect such injuries but they will be developed later by lightning strokes incidental to operation. Detection is difficult because of the short duration of the stroke. Long experience has shown us that in obtaining design data it is of the utmost importance to know when damage starts. This follows because the effect of lightning on partly damaged highly stressed insulation is cumulative.

A casual or superficial consideration of the subject would probably lead to the conclusion that the present A.I.E.E. tests should be abolished if lightning tests are established. Experience shows that such conclusions are erroneous. The tests at commerical frequencies are applied long enough to establish the strength of the major insulation, to detect manufacturing mistakes and, in case of over-stress, to indicate it by copious corona discharges. It is true that tests at operating frequency may also cause deterioration in poor designs, but such designs are easily detected by copious corona formation during such tests. Such discharges not only indicate high stresses but also a weak transformer for lightning. For example, corona between coils would indicate a design giving a high gradient between coils and short life under lightning. For this reason it has been our practise to design so that corona does not occur over the test range and to apply methods of detection of corona during tests.

F. W. Gay: The time is probably not far distant when all transformers to be used on high-voltage lines will receive a surge test and some manufacturers are even now waiting for the standardization of tests before purchasing one or more surge generators.

Transformers used on lines having arcover distances greater than 30 inches will probably be equipped with some means for assisting the equalization of stresses among winding turns and layers.

The electrical engineer is supplied by nature with three fundamental tools which he may use if he will in solving all his problems, *i. e.*, resistance, inductance, and capacitance. It is however, a characteristic of the electrical engineer to try and complete an undertaking while using only one of his tools.

It is entirely possible to provide a transformer with a resistance path in parallel with a winding to be protected and electrostatically couple the resistance path with the winding and with the transformer terminals, so that relatively very great currents will pass to charge the winding for high-frequency surges but relatively insignificant current will pass through the resistance at normal frequency.

It is also entirely possible to wind in juxtaposition with the many turn low-frequency high-voltage winding a surge winding of relatively very few turns and couple this high-frequency winding to the transformer terminals by condensers.

It is obvious that a shunt path of very low surge impedance is thus provided through the condenser and high-frequency few-turn surge winding. A surge of steep wave front will instantly pass through the condenser and pile up across the surge winding. The surge current will build up very fast in this surge winding and will induce a voltage in the low-frequency many-turn winding. This voltage in the low-frequency winding will serve to charge its turns and layers.

Mr. Palueff solves a problem in which the building up of the main magnetic flux in his primary winding is on the order of 2,000 microseconds. I propose to apply a surge winding about and close to a high-voltage winding having a corresponding time element on the order of a few tenths of one per cent as long; for example, having a time element on the order of say 10 microseconds instead of on the order say of 2,000 microseconds.

The time element required for voltage to build up on a secondary winding due to capacity effect between a primary and secondary winding is given for Mr. Palueff's transformer as on the order of 0.3 of one per cent of the long time element. With a surge winding such as I have outlined the distribution of voltage in the many-turn high-voltage winding, due both to inductance and capacitance, should be completed in a few hundredths of a microsecond.

A winding such as I have outlined should include in its circuit so great a series resistance that oscillation is completely damped. The success of such a surge winding requires:

1. The distribution of stress throughout the many-turn high-voltage winding so fast that substantially no oscillatory energy is stored in the high-voltage winding.
2. The natural period of oscillation of the surge winding designed so long that the many-turn high-voltage winding is able to maintain a substantially uniform voltage distribution as the voltage across the surge winding (relatively) slowly collapses to substantially zero.
3. Enough resistance in the surge winding to damp out oscillations. It would appear that considerable study could profitably be given to the use of resistance and reactance as a means of equalizing stresses in high-voltage transformers.

It is obvious that the above discussion applies primarily to those surge phenomena which Messrs. Palueff and Hagenguth classify under components 1 and 4.

In order to squelch components 2 and 3 more capacity must be used than can be justified for this purpose alone. It becomes necessary therefore to cause the capacity so employed to function also for power factor correction and voltage regulation; and to still further distribute costs a method of transformer winding switching has been developed whereby a substantial saving can be made in transformer material, and transformer efficiencies can be materially improved, while a single control is common to all the above functions. This switching of transformer windings becomes more important as transformer iron is improved and the per pound cost of iron with respect to copper tends to increase while the total copper loss to total iron loss ratio simultaneously increases.

In practise what amounts to a six-phase transformer is used to accomplish all the above results but for simplicity in the following explanation and to avoid design discussion six single-phase transformers are assumed as follows:

1. The six single-phase transformers are assumed to be designed for 13.2-kv. to 4-kv. operation at a magnetic density of 15,000 gausses. Each transformer is assumed to have permanently connected across its 4-kv. terminals a capacitor of 60 per cent of the transformer kva. capacity.

2. The above six transformers are permanently connected in pairs in series on the high side and in series on the low side and these three pairs of transformers are then connected in delta on a 13.2-kv. circuit high side and in delta on a 4-kv. circuit low side. With this connection all six transformers and their associated capacitors are operating at one-half voltage. The magnetic density in the transformer iron will then be 7,500 gausses.

3. A separate two-pole single throw switch is provided for each pair of series connected transformers. Those two high-voltage windings connected in series across two 13.2-kv. phase wires have their common junction point connected to one pole of the switch so that on closing, the common junction point is joined to the third phase wire and the two high-tension windings are connected in open delta by the closing of the switch. In a similar manner the two corresponding low-voltage windings connected in series across a corresponding two of the 4-kv. phase wires have their common junction point connected to one pole of the switch so that on closing, the common junction point is joined to the third 4-kv. phase wire and the two low-voltage windings together with their connected capacitors are thus connected in open delta.

By successively closing the three two-pole single-throw switches the three transformers and their associated capacitors are successively changed from half-voltage to double-voltage operation until when all three switches are closed both 13.2-kv. and 4-kv. windings and their associated capacitors are connected in parallel delta.

The following results are obtained.

1. Surges under the Palueff-Hagenguth 2 and 3 classification are squelched.
2. For a given 80 per cent power factor load the active material required in the transformers is less than half what would be required in a normal transformer of high light load efficiency.
3. The transformer losses are reduced for very light loads and for overloads and are substantially the same for intermediate loads.
4. Transformer reactances are reduced at heavy loads.
5. 13.2-kv. line carrying capacity is increased by improved power factor.
6. Voltage regulation may be obtained by controlling the closing of the three two-pole switches.
7. Economy of material is obtained by combining the above functions in one device.

L. V. Bewley: The authors have shown that the transient transmitted to the secondary circuit consists of three distinct components:

1. The initial very fast electrostatic impulse.
2. The long slow electromagnetic transient.
3. The oscillatory component, of small amplitude, oscillating about (2) as an axis.

They have further shown that each of these components may be considered separately, due to the great disparity in their time constants, and have gone into considerable detail concerning the electromagnetic transient.

Some time after the above development was made by the authors, I undertook a mathematical analysis of the internal oscillations in the primary and secondary windings of a transformer. It was found that complete solutions were possible only for grounded or isolated terminal conditions; but that the initial distributions could be found for general terminal impedances, and that the equations which determine the axes of internal oscillations reduce to those given in Part II of the paper by Palueff and Hagenguth. It is interesting to attempt a verification of their conclusions by deductions from the general equations given in my paper.* As stated in the closing discussion thereto, one of the principal uses to which these general equations may be put is to examine the validity of approximate equivalent circuits. In submitting this discussion I do not wish to convey the idea that I am adding anything essentially new, but merely to correlate the work of the authors with the general equations mentioned above.

THE ELECTROSTATIC COMPONENT

If both the primary and secondary neutrals are grounded, and the other secondary terminal is connected to a surge impedance z, then in the notation of my paper $Z_1 = Z_2 = O$, $Z_3 = z$, and by equations (**26**), (**27**), (**28**) and (**29**), there are:

$$\left.\begin{aligned}
E &= P\epsilon^{\alpha} + Q\epsilon^{-\alpha} + R\epsilon^{\beta} + S\epsilon^{-\beta}\\
O &= P + Q + R + S\\
O &= mP + mQ + nR + nS\\
O &= (1+a)\,mP\epsilon^{\alpha} + (1-a)\,mQ\epsilon^{-\alpha} + (1+b)\,nR\epsilon^{\beta} + (1-b)\,nS\epsilon^{-\beta}
\end{aligned}\right\}$$

in which $a = zK_1\alpha p$ and $b = zK_2\beta p$. Solving for the integration constants, and substituting in (**24**), there results for the secondary voltage:

$$e_2 = mn\left[\frac{\sinh\alpha x(\sinh\beta + b\cosh\beta) - \sinh\beta x(\sinh\alpha + a\cosh\alpha)}{n\sinh\alpha(\sinh\beta + b\cosh\beta) - m\sinh\beta(\sinh\alpha + a\cosh\alpha)}\right]E$$

At the terminal $x = 1$, the above equation reduces to

$$e_2 = mn\left[\frac{(\beta\sinh\alpha\,.\,\cosh\beta - \alpha\sinh\beta\,.\,\cosh\alpha)}{(n\beta\sinh\alpha\,.\,\cosh\beta - m\,\alpha\sinh\beta\,.\,\cosh\alpha)}\right]\frac{p}{p+\gamma}E$$

$$= \frac{E\,mn\,(\beta\sinh\alpha\,.\,\cosh\beta - \alpha\sinh\beta\,.\,\cosh\alpha)}{(n\beta\sinh\alpha\,.\,\cosh\beta - m\alpha\sinh\beta\,.\,\cosh\alpha)}\,\epsilon^{-\gamma t}$$

where

$$\gamma = \frac{(n-m)\sinh\alpha\,.\,\sinh\beta}{zK_2\,(n\beta\sinh\alpha\,.\,\cosh\beta - m\alpha\sinh\beta\,.\,\cosh\alpha)}$$

Now α and β are large enough in practical cases so that $\sinh\alpha \cong \cosh\alpha$ and $\sinh\beta \cong \cosh\beta$. Hereby the above equation simplifies to

$$e_2 \cong \frac{E\,mn\,(\beta - \alpha)}{(n\beta - m\alpha)}\,\epsilon^{-\frac{(n-m)t}{zK_2(n\beta - m\alpha)}}$$

Considering the case given in Mr. H. L. Rorden's discussion of my paper, and $z = 500$; there is $\alpha = 19.0$, $\beta = 11.7$, $m = -1.617$, $n = 0.618$, $K_2 = 1 \times 10^{-11}$. Then

$$e_2 \cong 0.193\,\epsilon^{-11.8t}$$

Thus the electrostatic component is an extremely short exponential impulse.

---

*A.I.E.E. TRANS., June 1932, p. 299.

THE OSCILLATORY COMPONENT

For a grounded neutral and short-circuited secondary the general equations (**53**) and (**54**) become (dropping subscripts)

$$e_1 = E + \Sigma\,(A\cos\omega t + A'\cos\Omega t)\sin\lambda x$$
$$e_2 = O + \Sigma\,(rA\cos\omega t + r'A'\cos\Omega t)\sin\lambda x$$

and from equation (**49**)

$$(i_{L2} + i_{K2}) = I_2 + \Sigma\,[\omega A\,(rC_2 + rC_3 - C_3)\sin\omega t$$
$$-\,\Omega A'\,(r'C_2 + r'C_3 - C_3)\sin\Omega t]\,\frac{\cos\lambda x}{\lambda}$$

where I_2 is an integration constant with respect to x and therefore a possible function of t. In Appendix II it is identified as the electromagnetic component of current. The oscillatory components are a maximum for $x = 0$ or $x = 1$ (the terminals). Now if the secondary is closed through an impedance the current will be *less* than that given above for a dead short circuit. Therefore the voltage transferred to the secondary by the oscillatory components can not exceed

$$e_2 = zi \leq z\,\Sigma\left[\frac{\omega A}{\lambda}\,(rC_2 + rC_3 - C_3)\sin\omega t\right.$$
$$\left.-\,\frac{\Omega}{\lambda}\,A'\,(rC_2 + r'C_3 - C_3)\sin\Omega t\right]$$

In practical cases this is of the order of 1 per cent of E for $z = 500$ ohms. For example, in the case given in Mr. Rorden's discussion the fundamental component of the above equation becomes

$$e_2 \leq 0.0103\,E \text{ for the fundamental } (s = 1)$$

THE ELECTROMAGNETIC COMPONENT

The basic equations used by the authors in their investigation of the voltage and currents transmitted to the secondary are identical with the ordinary conventional equations of the transformer. However, they point out the difficulty of arriving at accurate numerical results using self and mutual inductances, and have circumvented this difficulty by showing how these equations for mutually coupled circuits may be replaced (on a 1:1 turn ratio basis) by a simple series inductance, which approximation tremendously simplifies the calculation of the electromagnetic transient. In Appendix II of my paper* it is shown that their basic equations are a natural consequence of the general differential equations of the complete circuit of the transformer (involving distributed inductances and capacitances). I would point out that while in my paper complete solutions are obtained only for zero and infinite terminal impedances, that the particular derivation given in Appendix II is general, and applies to any terminal conditions; so that the currents fixing the axes of oscillations are on conformity with the relationships

$$\left.\begin{aligned} E &= p\,(L_1'I_2 + M'I_2) + Z_1 I_1 \\ O &= p\,(M'I_1 + L_2'I_2) + (Z_2 + Z_3)\,I_2 \end{aligned}\right\}$$

The secondary terminal voltage is a maximum when it is open-circuited ($I_2 = 0$), in which case for a grounded neutral it is in the turn ratio:

$$e_2 = \frac{M'}{L_1'}\,E \cong \frac{n_2}{n_1}\,E$$

But under this condition the electrostatic component persists for a much longer time, so that the secondary terminal voltage will be in excess of that given by the turn ratio, and should be insulated accordingly. When the secondary is open-circuited, the general equations describe the complete transient.

THREE-PHASE BANKS

In order to determine the effect on the secondary voltage of the transformer bank connection, and the number of phases struck by lightning, the authors reduced each particular connection to an equivalent circuit and then solved these equivalent circuits. Two examples are given in their Fig. 9, one of which is discussed in Part I of their paper, and the equations for the other derived in Part II, equations (**10**), (**11**), (**12**) and (**13**). However, it is not at all necessary to reduce to equivalent circuits, and considerable time can be saved by writing the equations directly from the bank connections. The two cases which they discuss in detail will suffice as illustrations:

Fig. 9a. Writing the voltage drops from phase a to phase b directly from the bank connection, there is

$$(2E) = (Z_1 + pL_s + 0.5pL_s + 0.5Z_1 + 3Z_2 + 1.5Z_2)\,I$$

and the secondary voltage is

$$e_2 = \frac{1.5IZ_2}{r} = \frac{(2E)}{r}\,\frac{1.5Z_2}{1.5\,(Z_1 + pL_s + 3Z_2)}$$
$$= \frac{(2E)}{r}\,\frac{q}{1 + 3q}\left(1 - \epsilon^{-\frac{Z_1}{L_s}(1+3q)t}\right)$$

Fig. 9b. Let the current in phase a be I and that in phase b be aI. Then writing the voltage drop from phase a to phase b directly from the bank connection, there is

$$(2E) = [Z_1 + pL_s - aZ_1 - apL_s + (1 - a)\,2Z_2 + (1 - a)\,Z_2]\,I$$
$$= (1 - a)\,(Z_1 + pL_s + 3Z_2)\,I$$

and the secondary voltage is

$$e_2 = \frac{IZ_2\,(1 - a)}{r} = \frac{(2E)}{r}\,\frac{(1 - a)\,Z_2}{(1 - a)\,(Z_1 + pL_s + 3Z_2)}$$
$$= \frac{(2E)}{r}\,\frac{q}{1 + 3q}\left(1 - \epsilon^{-\frac{Z_1}{L_s}(1+3q)t}\right)$$

Incidentally, it may be mentioned that neither the procedure followed by the authors, nor that given above, takes cognizance of the fact that traveling waves on the transmission lines affect each other through the mutual surge impedances.

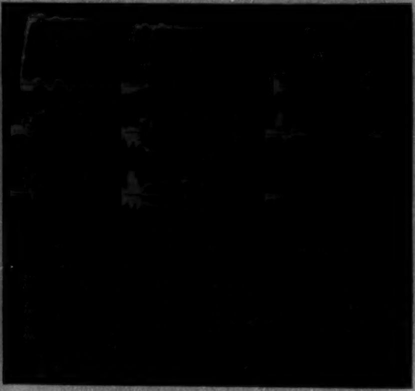
K. K. Palueff: Such tests as those suggested by Mr. Peek are very desirable indeed; they would weed out unsuitable transformer constructions. The principal difficulty in adopting an impulse test, as it appears to me, is to find reliable and positive methods of determining the effect of the test on all parts of transformer insulation. This is important because of the possibility of local damage resulting from such a test in transformers not properly designed or manufactured. Such damages, while of prime importance from the standpoint of the dielectric strength of the transformer, are often so extremely small physically that it is exceedingly difficult to locate them, or even to detect their presence.

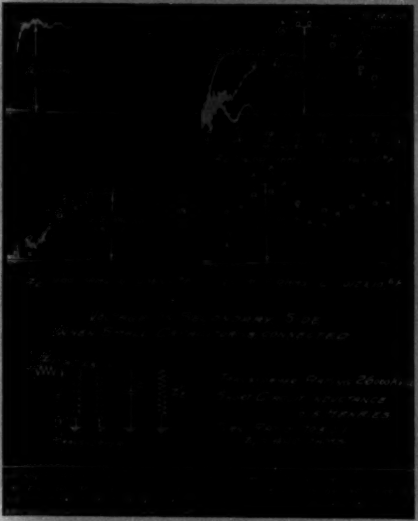
For example, on some occasions in the past upon examining transformers damaged in service by lightning, I observed, in addition to the principal damage, which is generally augmented by subsequent power flow through the short-circuit, numerous "pinhole" punctures of the insulation. These holes could not be detected without complete disassembly of the transformer and the use of an especially bright light.

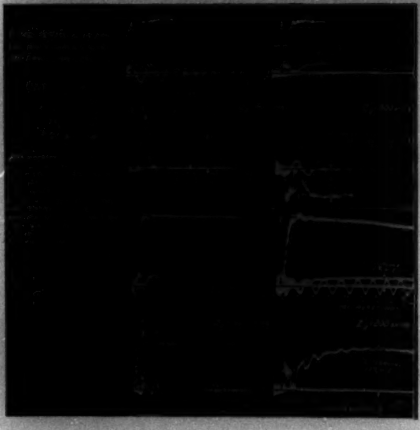
I fear that Mr. Gay's method of protection of the main transformer winding by means of an auxiliary or shunt winding connected to the terminals of the high-voltage winding through a capacitance, may prove to be not only impractical but also undesirable, as it would cause a substantial increase in the local voltage stresses in the main winding of the transformer. On account of this possibility I would suggest that Mr. Gay work out a numerical example of application of his device to an arbitrarily chosen transformer, showing at least the order of magnitude of the effect of the protective scheme.

---

*Loc. cit.







Several years ago, we were confronted with the problem of the transmission of lightning through transformers and autotransformers. Considering the phenomenon which takes place within the transformer winding in its entire complexity, it became obvious that a general solution, permitting computations with engineering accuracy, was not possible. Consequently, we directed our efforts toward evaluation of the relative practical importance of the four components discussed in the first part of the present paper. The considerations presented led to the conclusion that the electromagnetic component dominates the phenomenon. Once this was understood, the solution of the problem became not only mathematically elementary but sufficiently accurate numerically as to be used in practise as shown in the paper. The results of this solution were presented by me in January 1931. (See reference 5 of the bibliography.) On account of space limitations it was impossible at that time to include the material of the present paper.

While Mr. Bewley's paper is devoted to the study of transient voltages *within* transformer windings, our present paper deals with transient voltages that get *through* a transformer to secondary circuit. For this reason, Mr. Bewley's discussion is particularly interesting as it ties these two papers together.

The chief limitations of Mr. Bewley's solutions for oscillatory and electromagnetic components lie in the practical impossibility of sufficiently accurate evaluations of some principal constants (like L_1, L_2, M). This essentially limits the practical applications of these solutions.

His solution for electrostatic components, I believe is quite satisfactory for windings concentrically located, but not for windings that are interleaved. In the latter case capacity constants like K_1, K_2, C, C_2, C_3 can not be analytically determined. For a number of years, therefore, we were obliged to use an entirely different method for the calculation of this component. The results of this calculation were published in my previous papers and discussions.

It is my conviction that while equivalent circuits are rarely necessary for the solution of a problem, they are extremely helpful in visualizing and describing the phenomenon. It is for this reason that the equivalent circuits are given in this paper.

The oscillograms of this discussion illustrate the relative importance of the four components. They also show the degree of agreement between the calculations made in accordance with simple equations given in our paper and the actual values measured.

The Proximity Effect

Its Application to the Concentration of Heating Currents in Predetermined Strips

BY EDWARD BENNETT*

Fellow, A.I.E.E.

Synopsis.—*This paper describes methods of concentrating heating currents used for any industrial operation, such as welding, in predetermined strips of conducting plates, pipes, or other shapes. The method is to so place the shapes in close proximity to each other, or to auxiliary conductors, and to so interconnect the shapes with sources of alternating, or oscillatory, current of moderately high frequency that the heating current concentrates largely in adjacent strips in close proximity, in which the current flows in opposite directions in the two adjacent strips. Briefly stated, the method is to use an enhanced "proximity effect" to control the distribution of heating currents in bodies.*

The paper contains curves which have been worked out to illustrate the control of the distribution of the heating current densities by means of the proximity effect.

I. The Proximity Effect

Any variation in the value of the electric current in a wire is attended by, or has associated with it, a definite distribution of induced *electric intensities* at all points of the surrounding space. The value of the induced electric intensity at the point P which is associated with variations in the current in the wire W of Fig. 1 may be computed as follows. Divide the wire into segments, each so short that it may be regarded as a short straight filament. Take the vector contribution, F, to the electric intensity at P which is made by each short segment of wire of length s to be as expressed by equation (1), and find the vector sum of the contributions of all the segments which make up the wire W.†

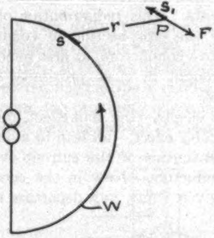


Fig. 1—Electric Intensity Due to a Segment of Current

$$\mathbf{F} \text{ (volts per cm.)} = -\, \mathbf{s}_1 \frac{\mu_o\, s}{4\, \pi\, r} \frac{di}{dt} \text{ (amperes) (sec.)} \qquad (1)$$

μ_o represents the permeability of free space in weber ampere-turn cm. units. $\mu_o = 4\,\pi\,10^{-9}$

$\mathbf{s}_1$ represents a unit vector parallel to the segment s and pointing in the arrow direction along s.

The significant features of this relation are that the electric intensity at P associated with the current in the segment is directly proportional to the *rate of increase* of the current, *inversely proportional to the distance* r from the segment to the point P and is parallel with but in a direction *opposite to the direction of acceleration* of positive charge in the segment.

By applying equation (1) to compute the electric intensity at a point P, (Fig. 2) lying close to a long straight filament of current and in its mid plane, the following expression is derived for the electric intensity:

$$\mathbf{F} \text{ (volts per cm.)} = -\, \mathbf{s}_1 \frac{\mu_o}{2\,\pi} \log \frac{s}{h} \frac{di}{dt} \text{ (approx.)} \qquad (2)$$

If the current flowing in these filaments is the sinusoidal current,

$$i = I \sin 2\,\pi\, f\, t \qquad (3)$$

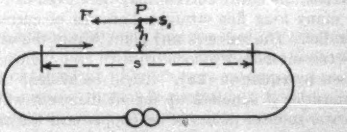

Fig. 2—Electric Intensity Due to a Long Straight Filament of Current

the expressions for the induced electric intensities accompanying this current become,

$$\mathbf{F} \text{ (volts per cm.)} = -\, \mathbf{s}_1 \frac{\mu_o\, s\, f\, I}{2\, r} \cos 2\,\pi\, f\, t \qquad (1a)$$

and

$$\mathbf{F} \text{ (volts per cm.)} = -\, \mathbf{s}_1\, \mu_o\, f\, I \log \frac{s}{h} \cos 2\,\pi\, f\, t \text{ (approx.)} \qquad (2a)$$

---

*Professor of Electrical Engineering, University of Wisconsin, Madison, Wis.

†The fact that the electric intensities existing at P at the instant t are to be found from the value of di/dt in the segment at an instant r/c seconds earlier than the instant t, has been omitted from this statement. It is not material to the situation to be discussed.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wis., March 14-16, 1932.

In other words, a long straight filament of alternating current is attended by induced electric intensities, or electric forces, which tend to cause current to flow in all neighboring conductors in a direction *opposite* to the direction of increase of the current in the filament. These forces increase in direct proportion to the increase in the frequency of alternation of the current, and increase in logarithmic fashion as the point P is taken closer to the inducing current filament.

The induced electric intensities, whose relation to the current is expressed by equation (**1**), serve to account in a quantitative way for such electrical effects as transformer action between primary and secondary coils, the *skin effect*, the *edge effect*, and the *proximity effect* in conductors carrying alternating currents.

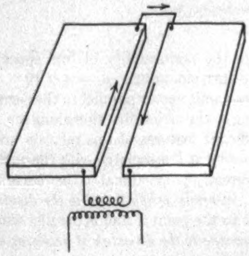

FIG. 3—CONNECTIONS FOR HEATING EDGES OF PLATES

Consider, for example, a long straight wire carrying an alternating current and let us suppose that the alternating current is uniformly distributed over the circular cross-section of the wire. For the purpose of computing the induced electric intensities within the body of the wire which attend the variations in the current, the entire current may be viewed as consisting of many long fine straight filaments of current all in parallel. The value at any point within the wire of the electric intensities associated with each filament is that given by equation (**2a**). It will be evident that these intensities if summed up for all filaments will yield a greater sum for points in the copper near the axis of the wire than for points more remote from the axis. That is to say, filaments near the axis are subject to greater induced electric intensities than filaments more remote, and these intensities are directly proportional to the frequency of alternation and at each instant are in a direction tending to lessen the rate of increase or decrease of the current. It follows that the current densities will be higher in filaments near the outside surface of the wire than in filaments near the axis. At high frequencies, this effect is so pronounced in conductors of large cross-section that an alternating current is confined to the filaments lying in a thin surface layer or *skin*, and the effect is called the *skin effect.*

If the alternating current flows in a conductor whose cross-section is a long narrow rectangle, as in a bus-bar of thin wide strap copper, it will be evident from the above considerations that the current densities will be much higher near the two edges of the rectangle than near the central portion of the strap. This increase in the current density toward the edges of rectangular sections is called the *edge effect.*

If now two long wires parallel each other, and if the wires constitute the outgoing and return conductors of an alternating current circuit, then at each instant of time the currents in the two conductors are opposite in direction. Accordingly, an increase in the current in conductor A results in induced electric forces in the filaments of conductor B which are in the direction in which the current in B tends to increase. But equation (**2a**) shows that these forces are greatest in the filaments of B which lie closest to A. In like manner the current B gives rise to assisting electric forces in the filaments of A. It follows that the current densities will be higher in the closely adjacent filaments of two circular conductors than in the more remotely separated filaments. The less the separation of the conductors and the higher the frequency, the greater will be the variation of the current density from the closely adjacent to the more remote filaments. This redistribution of the current densities over the cross-section of conductors which occurs when two conductors, at first remote from each other, are brought in close proximity is called the *proximity effect.*

These three effects,—the skin effect, the edge effect, and the proximity effect,—all lead to a departure from a uniform distribution of the current over the cross-section of conductors. Now in the conduction of a current of a given value, any departure from uniform current densities over the cross-section of homogeneous conductors means that the so-called I^2R loss, or the Joulean power expenditure, in the conductors is greater than for uniform densities. It is this wasteful aspect of these effects which seems to have led to many of the mathematical and experimental studies which have been made of the distribution of alternating current densities in conductors. It would seem that, in the main, the proximity effect has hitherto been viewed as an undesirable wasteful effect, and that thought and effort has been principally directed toward the minimizing of the effect.

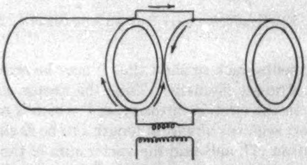

FIG. 4—CONNECTIONS FOR HEATING ENDS OF PIPES

II. THE USE OF THE PROXIMITY EFFECT TO CONCENTRATE HEATING CURRENTS IN PREDETERMINED STRIPS

While considering existing methods of welding pipe, it occurred to the author that the proximity effect could readily be magnified or enhanced to the point at which it might serve a very useful purpose in such industrial heating operations as those involved in welding, forming, hardening, etc. In heating operations requiring the heating of predetermined strips of conducting bodies or structural shapes, the proximity effect may be used to confine an electric heating current to these strips.

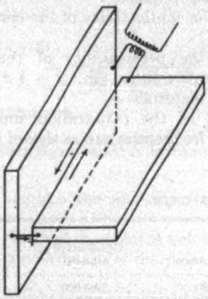

FIG. 5—CONNECTIONS FOR HEATING AN EDGE AND A STRIP

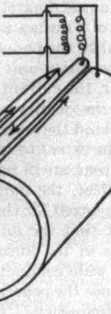

FIG. 6—CONNECTIONS FOR AN AUXILIARY CONDUCTOR WHICH DETERMINES THE PATH OF THE HEATING CURRENT

The confining of the heating currents to predetermined strips is accomplished by using heating currents whose frequency is in the range known as the audio range and by the electrical connections and the space arrangements illustrated in Figs. 3 to 8. An examination of these arrangements will show that they may be grouped under the following classification.

CLASSIFICATION OF CONNECTIONS FOR APPLYING THE PROXIMITY EFFECT

I. Current conductively conveyed to the body to be heated.
  A. The shapes and the connections of the heated bodies alone determine the strips in which the current concentrates. See Figs. 3, 4, and 5.
  B. An auxiliary water-cooled conductor is used to determine the strips of concentration. See Figs. 6 and 7.

II. The current is *induced* in the strip to be heated. (A water-cooled inducing coil lies in close proximity to the strip and there is no conductive connection with the body to be heated.) See Fig. 8.

The connections and the relations illustrated by the figures are so clear that they require little explanation. In each diagram, the transformer symbol represents the source of audio frequency current. The arrows represent the directions of the currents at a given instant of time in the different parts of the path. For the sake of clearness, it has been necessary to draw the parts with some considerable distance between the adjacent edges, but in the actual equipment this gap is of the order of a few millimeters or centimeters depending upon the thickness of the edges. Fig. 3 shows an arrangement in which the heating current is confined to layers a few millimeters to several centimeters deep along the adjacent edges of two steel plates. In Fig. 4, the heating current is confined to similar layers on the ends of two steel pipes. In Fig. 5, the heating current is confined to the edge of one plate and to a strip extending along the middle of the second plate.

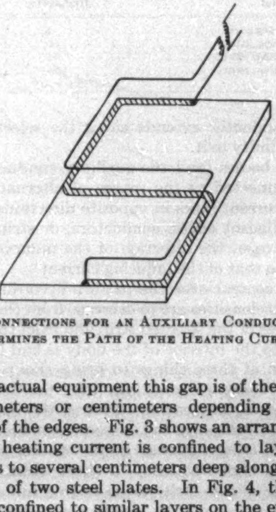

FIG. 7—CONNECTIONS FOR AN AUXILIARY CONDUCTOR WHICH DETERMINES THE PATH OF THE HEATING CURRENT

Figs. 6 and 7 show arrangements in which an auxiliary water-cooled tubular conductor is connected in series with the body to be heated. This auxiliary conductor parallels the strip to be heated in close proximity to it and thus serves to bring about the desired concentration of the heating current in the strip. The first sight of the red-hot strip of steel conforming to the sinuosities of the water-cooled copper tube mounted above the steel plate illustrated in Fig. 7 is found to be somewhat startling even to engineers who have witnessed the heating effects obtained with the Figs. 3, 4, and 5 arrangements.

The two views in Fig. 8 serve to illustrate the group of arrangements in which no conductive connection is made with the body to be heated. In this group an inducing current of suitable frequency flows in a tubular water-cooled inducing coil. By mounting this coil so that the entire coil or one leg or segment of the coil lies in *close proximity* to the strip, heating currents are induced along the selected strip.

It will be seen that the features common to all of these arrangements are as follows:

a. The strip of the conducting body in which heating current is to be caused to concentrate is selected and predetermined by so shaping, proportioning, and mounting another electric conductor that some portion of this second conductor extends along the selected strip in close proximity to it.

b. The bodies (and the auxiliary conductor, if any) are so connected to the source of alternating current that the current flows in opposite directions in the two closely adjacent edges, conductors, or strips. (In the inductive case, the direction of the induced current is opposite to that of the inducing current.)

c. The control over the pattern according to which the current densities are to decrease from the center line to the edges of the selected strip and from the surface of the strip to the interior of the body is had by the joint adaptation of three things to bring about the desired pattern. These three things are, the frequency of alternation of the heating currents, the distance from the surface of the strip to the second conductor, and the width and cross-sectional shape of this second conductor. A high frequency, a short distance between the surface of the strip to be heated and the second conductor, and a narrow second conductor lead to the concentration of the heating current in a narrow strip.

III. Illustrations of the Control Over the Distribution of the Current Densities

In dealing with the distribution of alternating currents over the cross-section of conducting bodies, it is very helpful to express all linear dimensions, not in centimeters, but in terms of a unit of length appropriate to this problem. We will call this unit of length the *penetration unit* for the material at the frequency in question. The advantage of using this unit is that it enables us to represent the distribution of the current for a wide range of conducting materials, spacings, and frequencies by a few curves.

The length of the *penetration unit* is,

$$1 \text{ P. unit (penetration unit) (in cm.)} = \frac{1}{\sqrt{\pi f \mu \gamma}} \tag{4}$$

f represents the frequency.

γ represents the conductivity of the conductor in mho-cm.

μ represents the permeability of the conductor in weber ampere-turns cm. $\mu = 4\pi\ 10^{-9}$ for non-magnetic materials.

The values of the penetration unit for different materials and frequencies are as shown in the following table.

TABLE I—VALUES OF THE PENETRATION UNIT

Material	Relative Resistivity	Relative Permeability	Frequency	Conductivity mho-cm.	P. unit cm.
Copper 20 deg. cent	1	1	960	580,000	0.214
Steel 20 deg. cent	11	100	960	52,700	0.070
Steel 800 deg. cent	94	1	960	6,240	2.06
Steel 1,300 deg. cent	100	1	960	5,800	2.14
Earth	5.8×10^9	1	60	10^{-4}	65,000

In order that a physical significance may attach to the penetration unit as defined in equation (4), the following statements may be noted. The effective resistance to an alternating current of frequency f of a conductor of circular cross-section whose radius is five or more times the penetration unit of the material at the frequency f, is approximately equal to the ordinary ohmic resistance of a surface layer of the conductor having a depth equal to the penetration unit. Again, at a depth of one penetration unit below the surface of such a large conductor, the current density is approximately 36.8 per cent of the density at the surface, and it lags by one radian behind the current density at the surface.

To illustrate the extent to which heating currents can be caused to concentrate in narrow strips by enhancing the proximity effect, the current densities have been worked out and plotted for the arrangement illustrated in Fig. 7, except that the auxiliary conductor has no sinuosities but is in the form of a long straight wire mounted over a wide conducting slab whose thickness is five or more times the penetration unit of the material at the operating frequency. The radius of the auxiliary conductor has been assumed to be very small in comparison with its mounting height h, say 5 per cent or less.

The current density C at any point A in the slab may be computed from the following Fourier integral.

$$C = \frac{j\,2\,I}{\pi} \int_0^\infty \frac{1}{\sqrt{b^2 + 2\,j} + b\,\mu_r} \cos xb \; exp\,(-\,hb - y\,\sqrt{b^2 + 2\,j})\, db \tag{5}$$

in which

- C represents the current density at A in amperes per square penetration unit.
- b represents the variable of the integrand. It disappears from the integral upon substituting the two limits 0 and ∞.
- I represents the value of the heating current in amperes.

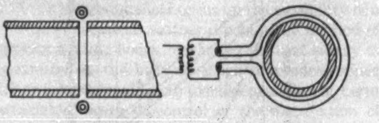

Fig. 8—Strip Heating by an Inducing Coil

- h represents the height of the auxiliary conductor above the surface.
- y represents the depth of the point A below the surface.
- x represents the x coordinate of the point A, as shown in Fig. 9.
- μ_r represents the relative permeability of the conducting slab.
- j represents $\sqrt{-1}$

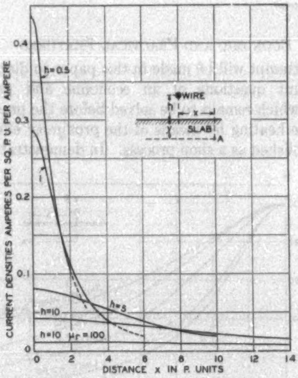

Fig. 9—Current Densities at the Surface of a Slab for Different Mounting Heights

Current densities are expressed in amperes per sq. penetration unit per ampere of heating current

The distances x and h are expressed in penetration units

$exp\ (-hb)$ represents the exponential series in $(-hb)$. (The values of x, y, and h are to be expressed in P units).

Equation (**5**) is valid for materials and frequencies in which the conduction current density is 100 or more times as great as the displacement current density. For copper at a frequency of 1,000 cycles per second, the conduction current density is 10^{15} times the displacement current density.

If the slab is of non-magnetic material or of ferromagnetic material at temperatures above the point at which the material becomes non-magnetic, μ_r has the value unity, and equation (**5**) reduces to a form equivalent to that given by Carson.[*]

$$C = -\frac{I}{\pi}\int_0^\infty [\sqrt{b^2+2j}-b] \cos xb \ exp\ (-hb-y\sqrt{b^2+2j})db \tag{6}$$

For mounting heights for the auxiliary conductor in which h is greater than 20 penetration units, equation (**6**) for non-magnetic materials evaluates to the simple form

$$C = \frac{1+j}{\pi}\ \frac{h}{h^2+x^2}\ (exp - y)\ (\cos y - j \sin y)\ I \tag{7}$$

An examination of Table I will show that the value of the penetration unit for steel at a frequency of 960 cycles per second lies between 0.07 cm. for steel with an assumed relative permeability of 100 and 2.14 cm. for steel at a temperature of 1,300 deg. cent. For an auxiliary conductor mounted at a height of one cm. above the conducting slab, the important range of mounting heights for this steel would lie between $h = 0.5$ and $h = 20$ penetration units.

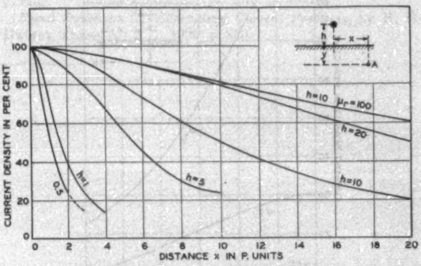

Fig. 10—Current Densities at the Surface of a Slab

For each height of wire, the current densities are expressed in per cent of the current density existing immediately under the wire at that height

The distances x and h are expressed in penetration units

Fig. 9 contains curves, each worked out for a different mounting height of the auxiliary conductor, which show the manner in which the current density at the surface of the slab falls off on each side of the center line of the heated strip. The values shown by the curves are the current densities in amperes per square penetration unit per ampere of heating current flowing in the slab. All the curves have been plotted for material in the non-magnetic state save the curve marked $\mu_r = 100$, in which the relative permeability has been taken to be 100. The curves in Fig. 10 likewise show the manner in which the current density at the surface of the slab falls off on each side of the center line, the curves in each case showing the current densities expressed in per cent of the current density immediately below the auxiliary conductor. In Fig. 10 the effect of the permeability of the steel in confining the current to a thinner surface layer of the steel and thereby causing a wider spread of the current is to be noted.

---

[*] "Wave Propagation in Overhead Wires with Ground Return," John R. Carson, *Bell System Tech. Jour.*, Oct. 1926.

A mounting height of one penetration unit means that the height of the auxiliary conductor above the slab would be about two cm. for a steel slab with a strip at its welding temperature and a 960 cycle heating current. For this important case, Figs. 11 and 12 show the distribution of current densities at the surface and at points in planes located at depths of one and two penetration units below the surface. These figures also show the phase of the current density at these points, relative to the phase of the (total) heating current. The current density along the center line of the strip is seen to be 60 deg. in advance of the total current. At points in planes one and two penetration units beneath the surface, the current density lags substantially one and two radians behind the current density at corresponding points on the surface, and has decreased to roughly $(1/\epsilon)$th and $(1/\epsilon)^2$ of its value at the surface. In the surface at a distance of two penetration units from the center line of the strip, the current density is seen to be 40 per cent of the value on the center line, and thus the power expenditure per unit volume is only 16 per cent as great as along the center line.

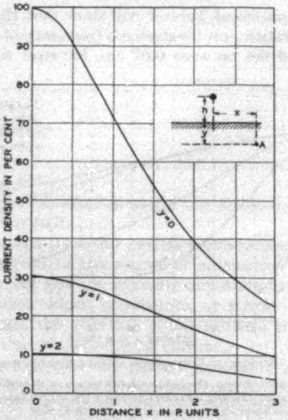

FIG. 11—CURRENT DENSITIES FOR A MOUNTING HEIGHT OF ONE PENETRATION UNIT

The current densities are given in per cent of the current density directly below the wire. x, y, and h are in penetration units

The relative effect of close proximity of the auxiliary conductor and of a high frequency of alternation in contributing toward the concentration of the heating currents in narrow strips is brought out more clearly by plotting the current densities at the surface against the ratio of the x distance of the filament to the mounting height h of the auxiliary conductor, as in Fig. 13.

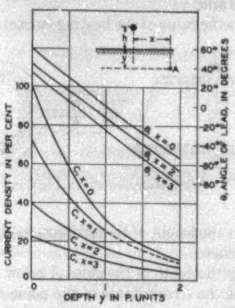

FIG. 12—CURRENT DENSITIES AND PHASE ANGLES FOR A MOUNTING HEIGHT OF ONE PENETRATION UNIT

The current densities are given in per cent of the current density directly below the wire

x, y, and h are in penetration units

The phase angles are the angles by which the current density leads the heating current

ECONOMIC AND PRACTICAL FEATURES

No attempt will be made in this paper to discuss the important questions of an economic and practical nature which remain to be solved before the practise of selective heating by means of the proximity effect can be established as a shop process. In demonstrating the method, the author has been limited to the experience to be had with a condenser-mercury-spark-gap source of high-frequency currents having a rating of 35 kw.

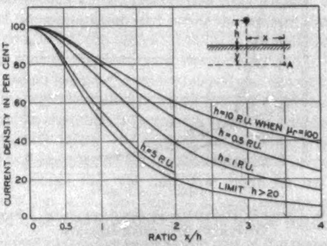

FIG. 13—CURRENT DENSITIES AT THE SURFACE OF A SLAB

For each height of wire, the current densities are expressed in per cent of the current density existing immediately under the wire at that height

The distance h is expressed in penetration units

The most economical range of frequencies for use in the process remains to be determined. Many factors which vary from operation to operation, such as the kind and size of material to be heated, the nature of the desired temperature pattern, and the relative cost of generating energy at the different frequencies will serve to determine the range of frequencies which will be the most economical. Present experience would indicate that the economic frequencies may be expected to center upon 960 cycles per second.

Unquestionably the control of the distribution of heating currents which is made possible by the application of the proximity effect opens up the possibility of a new range of industrial heating effects. The method of selectivity heating bodies by causing the heat energy to be generated in the body in strips of predetermined width and depth would seem to make possible a hitherto unattainable nicety of control of the distribution of temperatures in bodies. The control of the temperature patterns is obtained by adapting both the rate at which energy is supplied and the current density pattern to the desired end. For example, if in the welding of plates edge to edge, the induced heating current is for all practical purposes confined to a strip a few millimeters deep on the edge of the plate or plates, and if the power delivery is made large by using large inducing currents, portions of the plate a few centimeters from the edge may be substantially at room temperature when the edge reaches a welding temperature. On the other hand, if the energy is delivered at a more moderate rate, that is if smaller heating currents are used, the temperature gradient in the plate at the time the edge reaches a welding temperature may be made much more gradual. It will be seen that this control of the temperature patterns results from the fact that the application of the proximity effect makes it possible to confine the delivery of energy in rather definite fashion to predetermined strips of the body.

Toll Switching Plan for Wisconsin

BY W. C. LALLIER[1]

Associate, A.I.E.E.

***Synopsis.**—This paper outlines the general plan which is being employed in the handling of intrastate toll traffic of the Wisconsin Telephone Company, including many of the transmission features involved and touching upon the relationship of the plan to that for handling countrywide toll connections. A brief discussion is included of the present and proposed toll cable network in Wisconsin.*

THE growth in long distance telephone traffic has been rapid from the inception of the telephone business. Developments of telephone plant and technique have constantly extended the distance over which it is technically possible and commercially practicable to furnish toll telephone service.

The result of this extension in the range of transmission has been to increase the number of possible commercial toll connections and to stimulate growth in toll service. A graphic picture of the past and expected near future growth in toll business by five year periods is given in Fig. 1.

The enlarging field of toll telephone operations, together with the particularly rapid rate at which the long haul toll traffic has grown, requires that circuits be provided of such numbers, arrangements, and design as to permit the prompt establishment of the desired connections with a satisfactory grade of transmission. The general basis under which this is being accomplished is known as a toll switching plan. The toll switching plan for Wisconsin is outlined briefly in this paper, including some features of the transmission design requirements and the present and proposed toll cable network and the relationship of the plan to that for handling countrywide toll connections. A description of a toll switching plan for the Bell System was given in a paper* presented at the summer convention of the A.I.E.E., 1930.

The intrastate toll traffic in Wisconsin is composed of over 3,500 individual items, that is, traffic between two specific toll centers. Many of these traffic items are not of sufficient volume to justify direct circuits between the terminal exchanges and the traffic must therefore be switched at one or more points. In accordance with the toll switching plan, the switching of multiswitched toll traffic is generally restricted to selected toll centers arranged for introducing transmission gains into the switched connections and having toll circuits of such transmission characteristics connecting them to other toll centers as to facilitate the provision of reasonably low transmission losses between toll switchboards on connections within the State and on connections to points reached via the Bell System network.

When we speak of the net transmission loss (or net equivalent) of a toll circuit or a complete toll connection, we mean the net difference between the sum of the attenuation losses in the circuit or connection and the total transmission gain introduced by telephone repeaters. It may not at first be obvious why transmission gains are introduced at the switching points in switched toll connections, that is, why each of the links involved in the switched connections is not normally adjusted to have sufficiently low losses as to result in satisfactory overall losses on the complete toll connections without introducing transmission gains at the points of switching. The answer to this question lies in the fact that it is generally impracticable for noise, crosstalk or repeater singing reasons, as will be explained later, to work individual repeatered toll circuits to sufficiently low transmission losses. As an example, it would not be advisable to work a 2-wire cable circuit loaded with 88 millihenry coils spaced 6,000 ft. apart from Milwaukee to Madison to less than about 5 or 6 db. on terminal business for singing and crosstalk reasons, whereas it is practicable and desirable to work such a circuit to a loss of 1 or 2 db. when used as an intermediate link in multiswitched toll connections.

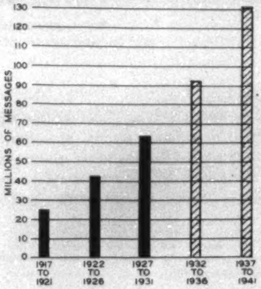

FIG. 1—TOTAL TOLL MESSAGES ORIGINATING IN WISCONSIN INVOLVING BELL SYSTEM CIRCUITS

There are two methods which are commonly used as a means of introducing transmission gain into switched toll connections, that is, the cord circuit repeater method and the pad control method.

The cord circuit repeater method, which employs special cord circuits containing telephone repeaters in connecting the various circuits together to form complete toll connections, has been used extensively in the past in providing improved transmission on switched connections. This is illustrated in Fig. 2. It has the disadvantage that the routine whereby the cord circuit repeaters are inserted into the switched connections by the toll operators is necessarily somewhat cumbersome, involving considerable expense for operators' labor and an increase in the time required to set up the switched toll connections. Furthermore, due to the human element involved, it is not possible to insure that the cord circuit repeaters will always be used when and as required by the routing instructions.

---

[1] Wisconsin Telephone Co., Milwaukee, Wis.

**A General Switching Plan for Telephone Toll Service*, by H. S. Osborne, TRANS. A.I.E.E., Oct. 1930, p. 1549.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wis., March 14-16, 1932.

The method which is now being employed in connection with all new repeater switching offices, and which is also superseding the cord circuit repeater method of operation in many existing cord circuit repeater offices, is the pad control method of introducing transmission gain into switched toll connections. In this method, terminal repeaters and suitable loss pads are provided in the toll circuits at the pad control switching offices and are so associated with relay equipment that the loss pads are automatically cut out of the toll circuits at the pad control switching office when two circuits are connected together in a switched connection. This method of introducing gain into switched toll connections is also illustrated in Fig. 2.

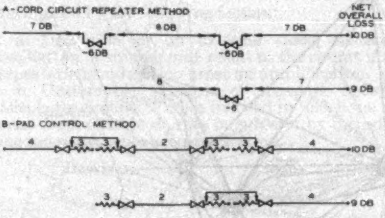

Fig. 2—Illustrations of Cord Circuit Repeater and Switching Pad Methods of Introducing Gain in Switched Connections

Two factors which have played an important part in justifying the extensive application of the pad control method of introducing transmission gains into switched toll connections are (a) important reductions which have occurred in the cost of terminal repeaters and (b) the substantial increase in the number of terminal repeaters required on toll circuits for other reasons such as, for example, in connection with the increased application of cable to the toll plant and the improved transmission efficiencies to which toll circuits are now generally being worked.

When the switching pad arrangement for gain control is employed at a switching office, pads are generally provided on all toll circuits which may be switched at this office in order to avoid repeater singing or undesirable noise or crosstalk effects when the circuits are used for terminating business. These pads are generally adjusted to have a loss of 3 db. except as higher loss values appear desirable to avoid noise, crosstalk or repeater singing or except as lower loss values are desirable to meet satisfactory transmission loss requirements and are satisfactory from the standpoint of noise, crosstalk, and repeater singing.

Switching Arrangements of Plan for Intrastate Traffic

The next item which will be discussed is the arrangement of switching offices and circuit groups employed in accordance with the toll switching plan for intrastate traffic.

Several primary switching points called "primary outlets" have been selected which are completely interconnected with direct circuit groups. Every toll center is to be provided with direct circuits to at least one of these primary outlets. With this arrangement, connections between any two toll centers can be handled with not more than two switches. As indicated in Fig. 3, the primary outlets which have been selected in Wisconsin are located at the following offices, each of which is a telephone repeater office and is arranged for introducing transmission gain into switched toll connections: Appleton, Eau Claire, Madison, Milwaukee, Stevens Point.

A number of "secondary switching points" has been selected for handling items of traffic where the length of haul can be shortened or other economies obtained by switching traffic at other than the above primary outlets, and for alternate and emergency routes. Each of these offices is also required to be a telephone repeater office arranged for introducing transmission gain into switched toll connections and to have such direct circuits to primary outlets, secondary switching points, and other toll centers as are warranted. Referring to Fig. 3, the following offices are now secondary switching offices: Ashland, Green Bay, La Crosse, Marinette, Rhinelander, Rice Lake.

In addition to the points just mentioned, it will be noted that Duluth, Minnesota; Ironwood, Michigan; and Dubuque, Iowa, all of which are repeater offices equipped with switching pads, are considered as secondary switching points in the toll switching plan for Wisconsin.

The following additional offices are planned to be secondary switching points as soon as the necessary telephone repeater and switching pad arrangements are provided, and are shown as such in Fig. 3: Fond du Lac, Janesville, Lake Geneva, Prentice.

The toll centers which are neither primary outlets nor secondary switching points are called terminating toll centers. Switching at these toll centers is limited to such single switched connections as can be made without exceeding certain transmission limitations as illustrated in Fig. 4. It will be noted from this figure that the permissible overall loss between terminal toll switchboards is 10 db. where the toll terminal losses of the toll centers are each 7 db., and that correspondingly higher overall toll circuit losses are permitted in cases where the toll terminal losses are less than 7 db.

Relation to Switching Arrangements for Countrywide Connections

Each of the five primary outlets in Wisconsin is provided with direct circuit groups to at least one "regional center," which is a backbone switching point in the nationwide toll traffic network. The regional centers are analogous in the countrywide toll switching plan to the primary outlets in the plan for Wisconsin in that they are arranged for introducing transmission gains into switched toll connections and are to be completely interconnected by direct circuit groups. Fig. 5 shows the present arrangement of regional centers and primary outlets in the Bell System. Every primary outlet in the country is to be provided with direct circuits to at least one of the regional centers and every toll center in the country is to be connected to at least one primary outlet. With the complete realization of this plan, therefore, it will be possible to talk between any two toll centers in the country with a total of not more than four switches involving five toll circuit links.

Note: As shown in the code, circuit groups to Milwaukee are indicated by dots at the distant terminals

The regional center to which all of the primary outlets in this portion of the country are connected is Chicago. Most of the secondary switching points in Wisconsin have direct circuits to Chicago, in which case they may be considered as "secondary outlets" in the countrywide toll switching plan.

Transmission Requirements of Toll Switching Plan

As mentioned previously, the transmission loss of a toll circuit or complete toll connection is the net difference between the total attenuation loss in the circuit or connection and the total transmission gain introduced by telephone repeaters. In practise, the amount by which it is possible to decrease the transmission losses of toll circuits or connections by introducing repeater gains is limited by the following factors:

Fig. 4—Transmission Requirements of Toll Switching Plan for Wisconsin

a. Distortion or, in extreme cases, sustained oscillation or singing may result in the circuit if the repeaters introduce too great an amplification.

b. Undesirable amounts of crosstalk between telephone circuits or noise induced in telephone circuits from outside sources may result by introducing too much repeater amplification.

c. Disturbing effects may be caused by the amplification of echo currents, *i. e.*, those portions of the speech currents which are reflected back from the distant end of the connection or from intermediate points, if the repeater gains are such as to result in too low an overall transmission loss.

On the longer toll connections, echo considerations are almost always the controlling factor in determining the minimum overall transmission loss which may be employed, whereas on the shorter toll connections, repeater singing, crosstalk or noise considerations generally are controlling. This is due to the fact that the echo effects on individual circuits increase more rapidly with length than do crosstalk and noise, the disturbing effect of echo currents being governed to a large extent by the amount of time elapsing between the transmittal of the speaker's voice and the return of the echo currents. This time interval is directly proportional to the length of the circuit. Singing tendencies also increase at a rapid rate with increase in length on two-wire circuits but tend to be independent of length on four-wire cable and carrier telephone circuits, which are used to a large extent in circuits between the primary outlets, between primary outlets and regional centers, and between the regional centers. Furthermore, when two or more toll circuits are connected together, the echo effects of the individual circuits add together almost directly, whereas the effects of crosstalk, singing and noise in-

Fig. 5—General Toll Switching Plan

Location of points at present employed as regional centers and primary outlets in the United States and Canada crease at a much less rapid rate. It follows, therefore, that when toll circuits are connected together in multi-switched connections, the overall combinations can, in general, be operated at transmission losses as limited by echo effects. Therefore, in establishing satisfactory transmission efficiencies for overall toll connections in accordance with the toll switching plan, each link must be designed not only with a consideration of its contribution to the overall transmission loss on the connection, but also with a consideration of its "echo minimum working net loss," *i. e.*, its contribution to the minimum working net loss of the overall connection from the echo current standpoint.

Fig. 6—Transmission Requirements of General Toll Switching Plan Toll Circuits Used in Multiswitch Toll Connections

A. Figures above line indicate maximum transmission loss in db.

B. Figures below line in parenthesis indicate minimum echo net loss margins

It is apparent that some of the circuits in a complete toll connection may be operated at net equivalents less than their echo minimum working net losses, providing other circuits in the connection are worked at net equivalents greater than their echo minimum working net losses. In each case the algebraic difference between the net loss contributed by the circuit in the connection, and the echo minimum working net loss of the circuit, may be referred to as the "echo net loss margin" of the circuit. Thus, if certain circuit links in a complete toll connection have positive echo net loss margins, then other links may be permitted to have negative echo net loss margins in that connection, as long as the sum of the echo net loss margins of all of the links in the connection are in no case less than zero.

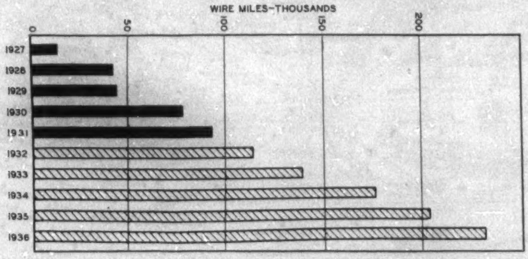

Fig. 8—Wire Miles of Toll Cable in Plant of Wisconsin Telephone Company

Fig. 6 shows the net equivalent and echo net loss margin requirements which have been set up for the various classes of toll circuits commonly used in multi-switched toll connections. These requirements were selected after a considerable study of the effects of various values of overall transmission loss upon the grade of service provided and upon the cost of providing the service, including comprehensive analyses to determine the most economic allocation from the Bell System standpoint of transmission losses and echo net loss margins among the various classes of toll circuits used in multiswitched toll connections.

Fig. 7—Toll Cable Layout in Wisconsin

With the transmission limitations indicated on Fig. 6, the maximum transmission loss between terminal toll switchboards on overall toll connections should not exceed 10 db. on intrastate traffic in Wisconsin involving a maximum of three toll circuits, or 17 db. on traffic involving a maximum of five toll circuits in the Bell System network.

TOLL CABLE NETWORK IN WISCONSIN

Fig. 7 shows the present and contemplated toll cable network in Wisconsin. It will be noted that many of the important cities are now connected by toll cable facilities. Within the next few years, it is expected that the cable network will be extended to provide an all cable route from Chicago and Milwaukee to St. Paul and Minneapolis over the Fox River Valley route to Appleton and thence west through Stevens Point and Eau Claire. In addition, future requirements will warrant extending this cable north from Appleton to Green Bay and Marinette and tying Sheboygan into the toll cable network by constructing a cable from Milwaukee along the lake shore route to Sheboygan. The future extension of toll cable south from Madison through Janesville and Beloit to Rockford, Illinois will link the southern portion of Wisconsin and the northern portion of Illinois to the toll cable network in Wisconsin.

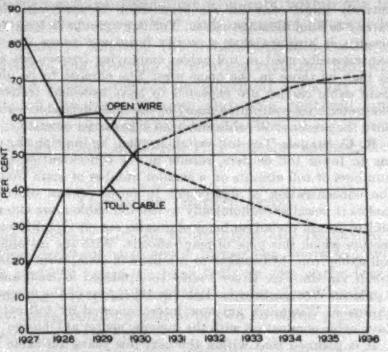

FIG. 9—PERCENTAGE OF TOLL WIRE MILES IN TOLL CABLE AND OPEN WIRE—WISCONSIN TELEPHONE COMPANY

It is apparent that the toll cable type of facilities is gradually supplementing or replacing the open wire type of facilities along many of the important backbone routes of the toll system. Ultimately, it is expected that the use of open wire lines will be limited largely to the feeder and branch routes to cities and towns located some distance from the main toll cable routes.

An idea of the rate at which the toll cable program has been going forward in the past few years is indicated graphically by Figs. 8 and 9. Fig. 8 shows the total wire-miles of toll cable in plant in Wisconsin and Fig. 9 shows the trend in the percentage of the total wire-miles in the toll plant which are in cable and in open wire.

The application of superimposed carrier systems to open wire lines has also been an important factor in providing for the increasing toll traffic during the last few years. Thus it may be seen from an inspection of Fig. 10 that a large majority of the principal open wire lines in the state now are arranged to have superimposed carrier systems operating on them.

Discussion

E. O. Neubauer: One of the important results of the application of the toll switching plan is the improved toll service to small communities located somewhat away from the larger cities. While the volume of toll traffic to and from these communities is comparatively small, it is necessary to include them in any plans for universal telephone service. As brought out in Mr. Lallier's paper a maximum of two switches and three toll lines is provided in the switching plans for complete intrastate service so that a satisfactory limit is automatically placed on the grade of toll service given to the smallest and most remote telephone exchange.

The large cities originate and receive such large volumes of toll traffic that large numbers of direct circuits are justified but the small community may have only a one circuit outlet. In Illinois under the toll switching plan, 87 per cent of the intrastate messages are completed over direct circuits, 12 per cent with one switch and only 1 per cent with two switches. It is this last 1 per cent of the traffic that is the largest beneficiary of the toll switching plan because previous to the switching plan there was no maximum limit to the number of switches and, therefore, no satisfactory service limit to the small community.

FIG. 10—PRINCIPAL TOLL CABLE, OPEN WIRE AND CARRIER ROUTES OF 1931—WISCONSIN TELEPHONE COMPANY

To make the switching plan fully operative, it is necessary only to have one connection from each terminal toll center to a primary outlet and to have the primary outlet interconnected. With these minimum requirements only 126 circuit groups would be needed to accommodate the 116 toll centers in Illinois. Actually there are over 500 such groups in service; the surplus groups affording more than one route between toll centers. The justification of these surplus groups is upon the basis of economy; *i. e.*, additional direct groups beyond the 126 must show economies in operation. Incidentally they afford a better grade of toll service than sought for under the switching plan. As the volume of toll traffic increases more of these surplus groups will be installed resulting in a gradual reduction in the number of messages requiring switches and a continuous improvement in toll service. However, to reach the other extreme would be to provide direct circuits between all toll centers but with 116 toll centers in Illinois, this would require nearly 6,700 circuit groups as against a little over 500 in service. The need for switching arrangements such as discussed in Mr. Lallier's paper is, therefore, a permanent one.

In regard to the replacement of cord circuit repeaters with the terminal repeaters and pads, this change in many situations has required a major investment and toll board rearrangement. Some offices showed ultimate savings by the conversion. These savings are brought about by the reduced number of toll positions required with a reduction in operating costs. Where ultimate economies could not be shown the conversion was made at Illinois switching points on the basis of the toll service improvements obtained with the pad system. Since the operation of the pads is automatic the operator is not required to determine the conditions under which pads are left in or removed as is the case with cord repeaters.

There are 4 primary outlets and 1 regional center in the switching plan for Illinois and all of these except one have already been converted. Centralia will be completed in the near future.

Glen Ireland: Although the general toll switching plan has only been in effect for about two years, sufficient progress has already been made and sufficient experience obtained to show conclusively that the advantages of such a plan are fully as great as expected. Only a few per cent of the circuit groups required to complete the routing arrangements of the general toll switching plan within the Bell System remain to be placed and these represent less than one per cent of the circuit miles now in service. Also, excellent progress has been made in providing terminal repeater-switching pad arrangements, which are mentioned in Mr. Lallier's paper, at the more important switching centers throughout the country, as is evidenced by the fact that all of the regional centers and over half of the primary outlets are now equipped with the improved arrangements. This provision throughout the system of the general switching plan arrangements, including the improved terminal repeater-switching pad arrangements, has been accompanied by material improvements in the quality of service on multi-switched connections which are, of course, the most difficult types of calls on which to provide satisfactory service. For example, the average speed of service interval on the multi-switched calls, that is, the time required from the placing of a toll call to the response of the called party or until a definite report is made by the operator, has been reduced by 45 per cent. Likewise there has been a marked improvement in transmission involving toll connections, particularly on the multi-switched toll connection.

In the latter part of Mr. Lallier's paper he points out a very interesting trend in the design of toll plant in Wisconsin which is also generally true throughout the Bell System, that is, that there has been a considerable increase in the use of toll cable and open wire carrier facilities. In this connection it is interesting to note that consideration has been given to and development is actively under way on the proposition of applying telephone carrier to long distance cables. For large groups of long distance circuits it appears that a carrier frequency range can be advantageously used in toll cables employing frequencies at least as high as those in the open wire. The circuits to be obtained from cable carrier are expected to have excellent transmission characteristics combining many of the most desirable features of both the present toll cable and open wire carrier circuits.

R. C. Siegel: The toll switching plan, by limiting the switching to fewer toll centers, results in the concentration of larger numbers of toll circuits on a smaller number of main routes and the concentration of equipment in fewer central offices. This makes it possible economically to use toll cable more extensively and to secure the advantages of greater circuit stability and protection which this type of plant affords. With the installation of toll cable from Milwaukee to Madison in 1928, from Milwaukee north via the Fox River Valley to Appleton in 1930 and from Appleton West to Stevens Point in 1931, four of the five primary outlets in Wisconsin are now interconnected by toll cable and have cable connection with the regional center at Chicago.

It is planned that within the next few years toll cable will be extended from Stevens Point west to Minneapolis, thereby completing the cable route from Chicago to Minneapolis and providing complete interconnection by means of toll cable of all primary outlets in Wisconsin. The construction of additional toll cables extending from these primary outlets to other important cities in Wisconsin is also contemplated in the future.

The procedure in reaching the objectives of the toll switching plan has been a gradual one and does not contemplate major replacements or rearrangement of plant, except those which may be required for other reasons. It is necessary, however, that the toll cable plant, central office buildings and telephone repeater equipment be so planned, constructed and arranged to permit of flexibly and economically caring for the requirements over a long period in the future.

Weather Resistant Covering for Line Wires

BY C. F. HARDING,* Fellow, A.I.E.E.
L. L. CARTER,* Associate, A.I.E.E.
and J. W. OLSON* Non-member

INTRODUCTION

THE problems involved in producing insulation for high-voltage cables have been of much interest to all electrical engineers for many years. Great advances have been seen in the art of producing insulation for higher voltage cables but it is only within the last two years that any unified and organized attempt has been made to improve the weathering and insulating qualities of the covering of weather resistant line wire. Previous to this time the development work lay in the hands of the manufacturer and was centered upon cutting costs to meet the demand for a cheaper product, which would meet the very meager specifications available.

ORIGIN OF INVESTIGATION

The concentration of effort upon the reduction of weather resistant wire costs during the years following 1918 or 1920 began to bear fruit in the early loss of saturating compound and the shedding of braids, in many cases, within a period of two to three years after the erection of the lines.

As more and more early failures of weather resistant wire coverings were seen to occur in extremely short lengths of time, the sentiments of many operating engineers swung toward discontinuing a weather resistant covering on overhead lines and adopting bare conductors for all service except where tree wire was necessary or where highly insulated conductors were required at points of inadequate spacing or clearance. Certain engineers opposed the policy of abandoning the use of weather resistant coverings on overhead lines of 4,000 volts line to line and less, for the reason that such a covering might reduce the number of service interruptions by preventing grounds and short circuits. This group believed that an attempt should be made to improve weather resistant coverings before making a decision to discontinue using such coverings.

At the insistence of the engineers among the companies represented by the Utilities Research Commission, that weather resistant wire coverings should be developed to provide longer life and higher insulating values, the Commission initiated a study of this problem at Purdue University. This study, Case 28, of the Utilities Research Commission was started October 1, 1929 under the direction of the Electrical Division of the Engineering Experiment Station with the Chemical Division cooperating.

PRELIMINARY INVESTIGATION OF PROBLEM

Shortly after the work was started a visit was made to the majority of the weather resistant wire manufacturing plants in the United States to observe the processes of manufacture, inspect the wire plant laboratories, and to discuss the problem with the men engaged in the production of weather resistant wire. This preliminary visit and discussion disclosed the fact that there was no adequate equipment available in the wire plants to test the comparative life of different weather resistant wire coverings and that there was only a meager knowledge of the reasons for early failure of weather resistant coverings and of means to increase the life of such coverings.

This preliminary survey emphasized the need for the purchase or construction of complete testing equipment at Purdue University.

ORGANIZATION AND EQUIPMENT OF LABORATORIES

The equipment purchased or constructed for this work includes apparatus for both accelerated and natural weathering of finished wires or wire covering materials and for complete physical and chemical tests of such materials. This equipment is being used to study the faults of present materials and to test new coverings and new materials.

The accelerated weathering equipment for testing the comparative length of life of completed wires, asphalts and other saturants, yarns, etc., exposes the samples to the light from a carbon arc and to a water spray at a constant wire temperature of 175 deg. fahr. during one part of the daily weathering cycle. The samples are subjected to freezing by moving the wire holding drum to a large refrigerator and to thawing and drying by moving back to the light exposure chamber. Distilled water is circulated to the sprays from a storage tank and pressure provided by an auxiliary pump.

A natural weathering rack for completed wires is located on the roof of the Electrical Engineering Building and provides continuous current loading and application of line voltage to the wire samples.

Service testing equipment for duplicating installation and service conditions on weather resistant wire includes apparatus for subjecting the wire to abrasion such as occurs when drawn over a cross arm, or that caused by rubbing on insulators, wrapping and bending at freezing temperatures, and for producing decentralization of the conductor in the covering such as occurs in service.

All the standard physical tests of asphalts, such as the determinations of softening or fusing point, viscosity at saturating temperatures, hardness at wire operating temperatures, and pliability at low temperatures are applied to weather resistant wire saturants.

---

*Purdue University, Lafayette, Indiana.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

The fusing point is determined by the standard ball and ring method used by the asphalt industry. According to this test the fusing point is the temperature at which a steel ball of specified weight drops through a mold of the material under test, supported on a brass ring and immersed in water, the temperature of which is raised at a slow and definite rate.

The viscosity of the asphalt at saturating temperatures is determined by the Stormer method. Viscosity, by this method, is expressed as the number of seconds required for 100 revolutions of a cylinder propelled by a 100-gram weight and immersed in the material to be tested. It may be seen that the higher the time required for 100 revolutions the higher is the viscosity.

The consistency or hardness is determined by use of the Abraham consistometer. This equipment measures the pressure required to force various size plungers into the material under test, at a constant rate. The ends of these plungers are flat circular disks of larger size than the body of the plunger so that there is no friction between the asphalt and the shank of the plunger. The higher the consistometer hardness number the harder is the material under test. This hardness number is defined as the third root of the number of grams which must be applied to a circular flat plate, one square centimeter in area, to cause it to displace the substance under test at the rate of one centimeter per minute.

The pliability at low temperatures is determined by bending a mold, of dimensions ¼ in. by 1 in. by 4 in., broadside about a round mandrel ⅜ in. in diameter while the sample and apparatus are held at the low temperature of test. The angle of bend is increased at the rate of five degrees per minute and the angle of bending required to break the mold is taken as a measure of the pliability.

MAJOR FAULTS OF PRESENT WEATHER RESISTANT WIRE COVERINGS LIE IN THE SATURANTS

The work at Purdue University indicates positively that the poor physical properties of the saturants used in weather resistant wire coverings in the past have been the cause of the extremely early failure of weather resistant wire. The coverings of wires which last well are eventually caused to fail by a combination of physical changes, by the saturants shifting in the coverings, etc., and chemical changes in the saturant caused by exposure to light, oxygen of the air, etc., but in very early failures the effects of light and oxygen are of less importance than the effects of poor physical properties which cause the saturant to shift in the braid when hot and to crack and split when cold.

These poor physical properties of the saturants are, namely, too low fusing points, extreme softness when warm, great changes in hardness with changes in temperature, extreme brittleness at even moderately low temperatures, and a marked tendency to evaporate. The majority of saturants used have had softening points (as determined by the ball and ring method) ranging from 130 to 150 deg. fahr., lower than maximum wire operating temperatures. These materials shift in the braids leaving the upper braids unprotected at ordinary summer temperatures, which are well below the fusing point. The extreme brittleness of these saturants, which results in cracking and breaking of the braids in cold weather, may be illustrated by the fact that less than two degrees bending is required to break molds of these saturants in the pliability test at 0 deg. fahr.

Many of the poor physical properties, particularly the disappearance or evaporation of the saturant from the braids, have been caused by the addition of excessive amounts of waxes, wax tailings or low melting fluxes to obtain fluidity and ease of saturation. This addition was usually made by the workman operating the saturating tank and resulted in a saturant of variable properties. These low boiling materials soon leave the saturant, causing the body of the asphalt to disintegrate. The saturants vary in their resistance to the weathering effects of light and oxygen and the worst are subject to excessive surface deterioration and erosion.

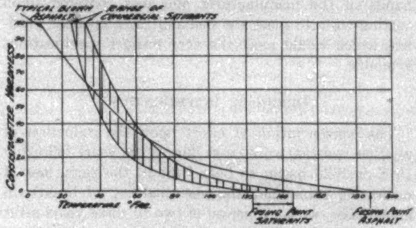

FIG. 1—COMPARISON OF INITIAL HARDNESS

The result of all these factors is the loss of compound, particularly from the upper side of the braids, with the resultant breaking of the braids on the upper side and the familiar festooning.

The use of materials subject to such faults has been permitted by specifications which did not specify the source nor physical properties of saturants. Proper specifications have not been written because of a lack of knowledge essential to the writing of such specifications. The work at Purdue University is to provide such a specification.

The commonly used drip and stain tests cannot be regarded as tests of the physical properties of the saturants. The high melting wax used as an outer coating prevents staining and the yarns hold the asphalt, preventing dripping, even though the saturant may be quite soft. The drip test may also favor an undersaturated wire.

Finishing waxes cannot be regarded as of great protection to the covering because they evaporate or crack and flake off within a short time or are damaged in installation. The wax has cracked, chipped off, or simply disappeared from the surface of the wire, on the various samples in the natural exposure rack, in from three to eight months.

COTTON YARNS

Have Minor Effect Upon Length of Life of Wire Coverings

It has been found that the cotton yarns are not so important in producing a long lived covering as are the saturants used. It is important, however, that sufficient cotton be present in the two inner braids to absorb and hold the saturant and that the outer braid should be closely woven to resist abrasion and erosion.

The one fault of the braided construction is that it does not, consistently, afford insulation beyond that of the air spacing provided, because of the interstices always present. It is desirable to have a more solid and homogeneous material next to the conductor.

IMPROVED SATURANTS

Intensive experimental work, in the past year and a half, with many asphalts of different types from different sources, tested in both accelerated and natural weathering exposures, has shown conclusively that the length of life of weather resistant wire coverings may be materially increased by using, for a saturant, blown petroleum asphalts having a ball and ring softening point of 180 to 200 deg. fahr., free of low boiling materials and without the addition of wax tailings in the wire plant.

Several of the weather resistant wire makers have offered to produce a quantity of experimental weather resistant wire on a commercial scale. It has been decided, therefore, to produce a carload of wire, using as a saturant, the asphalts which have been found to provide the longest lived wire coverings. This saturant will be a blown petroleum asphalt having the above range of ball and ring softening points; a hardness, as determined by the needle penetrometer, of 35-25 at 77 deg. fahr. with 100 grams loading for 5 seconds; chosen for the greatest pliability at low temperatures and for freedom from low boiling materials. The experience gained in the production of this wire will be an aid in the writing of a specification for an improved weather resistant wire covering.

Such an asphalt, of greater stability at higher wire temperatures, will greatly reduce the shift of the saturant in the braids and will be less subject to evaporation and erosion. In addition, these asphalts are less susceptible to temperature changes and are much less brittle at low temperatures. Such asphalts may be bent many degrees in the pliability test while commercial saturants cannot be bent more than two degrees.

The differences in hardness of these materials may be noted by referring to the hardness curves in Fig. 1. Table I gives comparative values for fusing point, hardness, pliability, and temperature susceptibility.

TABLE I—PROPERTIES OF COMMERCIAL SATURANTS COMPARED TO A TYPICAL BLOWN ASPHALT

	Range of saturants	Blown asphalt
Ball and ring fusing point	120–150 deg. fahr.	192 deg. fahr.
Pliability at 0 deg. fahr	½–1½ deg	23 deg.
Consistency-Abraham hardness:		
20 deg. fahr	Above 100	80
60 deg. fahr	17–40	35
100 deg. fahr	4–9	15
Loss by evaporation 100 hr. at 325 deg. fahr	0.25–4.0	none
Ball and ring fusing point after heating	190–230 deg. fahr	224 deg. fahr.
Consistency after heating:		
20 deg. fahr	above 100	95
60 deg. fahr	43–90	42
100 deg. fahr	18–55	18
Viscosity: Temperature at which a viscosity of 100 sec. per 100 rev. is obtained	260–278	357

The presence of undesirable low boiling fluxes and waxes is detected by testing the changes in the physical properties of the asphalts and measuring the evaporation after they have been heated at 325 deg. fahr. for 100 hours. It is expected that this test gives, in a short time, a measure of the changes which take place in the saturants in the wire covering, over a period of years. The changes taking place during heating have been of much help in eliminating the poorer saturants. The comparative changes with heating, for commercial saturants and a typical blown asphalt, may be noted by comparing Fig. 2 with Fig. 1.

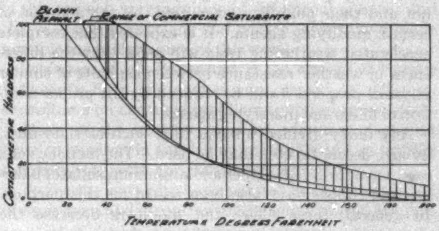

FIG. 2—COMPARISON OF HARDNESS AFTER HEATING

Heated 100 hours at 325 deg. fahr.

While the shifting of the saturants in the braids can be greatly reduced by choosing asphalts of the proper physical properties, such physical properties as may be checked in the laboratory in a few hours, and while saturants containing low boiling point materials can be eliminated by the heating test requiring several days, the accelerated weathering test is still required as a guide in choosing saturants least subject to weathering when exposed to light and air.

An exhaustive study of the manner in which asphalts weather, which have been selected from all sources and of different physical properties, is to be conducted to learn if it is possible to use only physical tests and the changes in their physical properties with heating as checks upon the life of such asphalts. If this is possible, then a specification for weather resistant wire which sets forth the properties of the saturant used will provide long life for such coverings. The asphalts can be tested within a reasonably short time to see that they meet the specification.

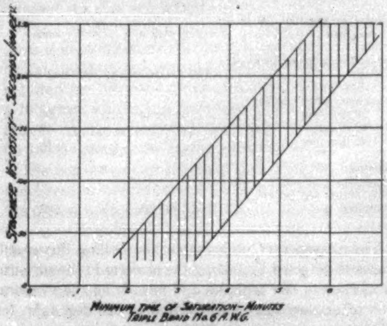

FIG. 3—RELATION OF VISCOSITY AND SATURATING TIME

MODIFICATION OF ASPHALTS

After asphalts of the proper physical properties have been chosen it will be found that these asphalts may be further improved, both in regard to their stability when hot and their pliability when cold, by the addition of certain modifying agents. It is expected that complete accelerated weathering tests will show that the differences in weather resistance between asphalts of similar physical properties will be reduced by the proper addition of fillers and modifying agents.

Any finely divided mineral filler such as slate dust, fly ash, dolomite, etc., may be used. The metallic salts used have included copper and aluminum sulfate; bakelite and rubber have also been tested for this purpose. In general, these fillers and modifiers decrease the changes in physical properties of the asphalts with changes in temperature and improve their resistance to the effects of weathering.

TEMPERATURES OF SATURATING BRAIDED COVERINGS *Must be Increased if Saturants of More Satisfactory Qualities are to be Used*

To obtain thorough saturation of triple braid coverings with saturants of a fusing point of 180 to 200 deg. fahr. at present saturating speeds it is necessary to use higher saturating temperatures than are used today. Laboratory tests have shown that to obtain saturation of three braids on No. 6 A. W. G. conductors in five minutes requires a saturant viscosity of 100 deg. Stormer or less. Fig. 3 shows graphically the time required to saturate the triple braid covering on No. 6 A. W. G. conductors with asphalts of a very wide range, at any given viscosity. It should be noted that the time of saturation is not the same for all saturants at a given viscosity but varies with the asphalt, some requiring more and some less time, as indicated by the shaded area.

Reference to Fig. 4 discloses that temperatures of 375 to 400 deg. fahr. are required to provide this viscosity in the case of a typical blown asphalt having a fusing point of 190 deg. fahr. A change would be required in the heating equipment for the saturating tanks in the wire plants, if such saturants are to be used.

SATURATING TEMPERATURES OF 400 DEG. FAHR. *Are Not Harmful to Cotton Yarns or Copper Conductors*

To determine definitely that saturating temperatures as high as 400 deg. fahr. can be used without damaging the cotton yarns nor too greatly annealing the copper conductors, a number of tests was made to determine the effects of this temperature.

The cotton yarns were tested for tensile strength, heated in air for different times, allowed to regain normal moisture content and again tested. The tensile strength of oil soaked yarns was also tested and compared with that of similar yarns heated in hot oil for varying times. No. 6 A. W. G. copper conductors, both medium hard drawn and hard drawn, were tested for tensile strength after heating in hot oil for varying times and compared with tests made on unheated conductors.

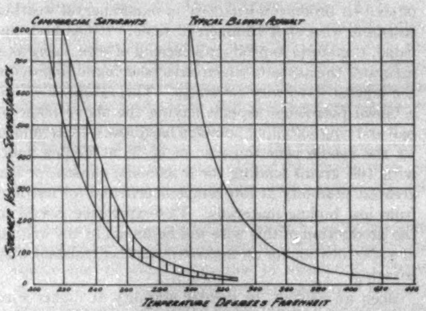

FIG. 4—COMPARISON OF VISCOSITY

The results of the cotton and copper tests are presented in Table II.

It may be seen that the loss of strength of the cotton yarn is of no importance in even the longest saturating time. There is no appreciable annealing of the copper conductors in the saturating time required in the modern continuous saturating tanks which are now generally used. In the case of the older type "reel in and reel out" saturating tank the time required for saturation

TABLE II—EFFECT OF SATURATING TEMPERATURE ON THE TENSILE STRENGTH OF COTTON YARN

Yarn heated in air (constant temperature oven)

Sample	Tensile strength	Loss	Per cent loss
Original yarn	2,001 gm.		
15 min. at 392 deg. fahr	1,760 gm.	241 gm.	12.0
30 min. at 392 deg. fahr	1,526 gm.	475 gm.	23.7
90 min. at 392 deg. fahr	1,360 gm.	641 gm.	32.0

Yarn heated in oil

Sample	Average tensile strength	Per cent loss		
		A	*B*	*C*
Dry yarn	1908 gm.			
Dipped in cold oil	1917 gm.			
Heated 15 min. 212 deg. fahr	1809 gm.	5.62		
Heated 30 min. 212 deg. fahr	1731 gm.	14.5	4.32	
Heated 15 min. 302 deg. fahr	1683 gm.	12.2	7.00	
Heated 30 min. 302 deg. fahr	1623 gm.	15.3	10.30	3.57
Heated 7½ min. 392 deg. fahr	1637 gm.	14.6	9.55	2.52
Heated 15 min. 392 deg. fahr	1593 gm.	16.85	11.98	5.35
Heated 30 min. 392 deg. fahr	1546 gm.	19.3	14.55	8.13

A Loss in strength considering the cold oiled sample as a standard.

B loss in strength considering the sample heated 15 min. at 212 deg. fahr. as a standard.

C loss in strength considering the sample heated 15 min. at 302 deg. fahr. as a standard.

All samples heated at 392 deg. fahr.

Kind of sample	Tensile strength lb. per sq. in.	Loss in strength lb. per sq. in.	Per cent loss
Hard drawn No. 6 copper wire			
Unheated wire	63,500		
Heated 10 minutes	62,590	970	1.53
Heated 30 minutes	61,140	2,420	3.96
Medium hard drawn No. 6 copper wire			
Unheated wire	51,430		
Heated 10 minutes	50,780	650	1.27
Heated 30 minutes	49,490	1,940	3.93

may be long enough to anneal the conductor slightly, requiring that the conductors be drawn somewhat harder initially.

These tests, it is believed, have definitely cleared the way for the use of higher saturating temperatures in so far as likelihood of any damage to yarns or conductors is concerned.

New and Different Types of Coverings

While the development work carried on thus far has been concentrated upon providing an improved asphaltic base saturant which could be applied to the present triple braid covering without great changes in the weather resistant wire plant, experimental work with other types of weather resistant saturants and with coverings other than triple braid, has been carried on.

Bakelite and other synthetic resins, Harvel compounds and varnishes, and other materials have been applied to weather resistant wire coverings. The use of these materials as saturants for a single outer braid, applied over an insulating cover on the conductor, provides a highly protective coating because of the excellent weathering quality of such materials.

Experiments with conductors having a paper tape covering next to the conductor and a single outer braid weatherproofed with these very high quality saturants have shown that coverings of consistently high insulating value can be obtained and that the paper next to the conductor does not deteriorate appreciably in the time of one accelerated weathering test.

Most of these high grade saturants can only be applied to one braid because of their high cost.

It is expected that future work will provide a weather resistant wire covering of higher insulating value and longer life than the present triple braid construction but of smaller size and weight. There are many interesting possibilities of improvement in this type of covering.

Conclusion

The present triple braid weather resistant wire covering may be materially improved by the use of higher fusing point blown asphalts, free of waxes and low boiling fluxes, as saturants. Such a saturant will provide a covering of uniformly long life.

It has been proved that the higher saturating temperatures required to apply such saturants may be used without damage to the cotton yarns or excessive annealing of the copper conductors.

Specifications for weather resistant coverings will soon be written as a result of this work, the terms of which will guarantee to the utility, weather resistant wire of long life.

Future work will provide a covering of lighter weight and smaller size but of higher insulating value and longer life than present construction.

Acknowledgment

Acknowledgment is gratefully extended to Mr. G. W. Hamilton, Chairman, and to the members of the committee of the Utilities Research Commission in charge of this project, in recognition of the encouragement and the valuable suggestions and advice which have made possible the performance of this work.

Professors H. C. Peffer and R. N. Shreve of Purdue University have rendered invaluable aid in acting as consultants on chemical problems involved in the work.

Many of the weather resistant wire manufacturers have cooperated in furnishing materials and in frankly discussing the work and its application to the plant.

To the students who have assisted in the construction of equipment and in routine testing many thanks are due.

Discussion

C. D. Brown: The development of an improved saturant for weather resistant covering of line wires is a decided step in the right direction and Mr. Harding is to be complimented for his research work on this subject.

In some cases, triple braid weatherproof insulation has little insulating qualities after it has been up for four or five years, and a great many companies do not place any confidence in this type of insulation on primary distribution feeders. The result is that many companies only use weatherproof insulation where it is required by the code, and their construction is such that reliable service can be maintained even though the insulation drops off entirely, except where tree conditions are encountered.

Tree wire is used under much less favorable conditions than the ordinary weatherproof wire and the weather resistant covering of tree wire must not only be depended upon to protect the rubber insulation against weather conditions but also against abrasion. If the insulation of tree wire fails, it often results in an interruption to service. Our experience has indicated that the outer covering of tree wire has in many cases the same deficiencies with respect to impregnating compound, as are brought out in the paper regarding weatherproof insulation.

Has any investigation been made of the properties of the weather resistant covering for tree wire, and if so, what have been the results of the investigation?

James H. Foote: It is indicated in the paper that seven years' life of weatherproofing on overhead wire would seem to be reasonable, and certain economic considerations given in the paper are based upon this life. In my experience this would seem to be an abnormally short period of time. I have in mind a distribution system which was entirely rebuilt in 1914 using triple braid weatherproof wire manufactured to no special specifications, which does not today after 18 years show any appreciable amount of raggedness or deterioration easily visible from the ground. In another city the entire street lighting system was rebuilt in 1917 using triple braid weatherproof wire obtained on the market, which today shows no deterioation visible from the ground after 15 years of life.

The question may arise as to whether the results obtained with the lighter braids ordinarily used on the smaller sizes of wire used by the authors of the paper in their experiments will also apply to the considerably thicker cotton covering usually applied to the larger sizes of wire ordinarily used in distribution, such as 0 or 0000 A.W.G.

It is mentioned in the paper that many engineers have swung towards discontinuing the weather resistant covering on overhead lines. While it would seem that the omission of insulating covering may well be justified on the higher voltage conductors, especially primary lines of over 5,000 volts, still the weatherproofing has a real value as insulation in the case of overhead secondary lines run on close spacing such as is common where secondary racks are used instead of crossarms, and especially where the secondary lines are run through trees where the tree branches may push the wires together during storms. It would seem entirely reasonable to omit the weatherproofing from the neutral wire of a three-wire secondary, leaving the weatherproofing on the outside wires. Service wires should also have weatherproofing or other insulation since they very frequently are so strung as to swing together under certain conditions. Thus, there appears to be an adequate market for weatherproofed wire in the future and it would seem that the investigation carried on by the authors is certainly very well worth while.

Frank Kingburne: While some of the findings may be revolutionary, largely because of the dearth of available information, this centralized, unbiased research should excite the manufacturers toward improving the general character of this phase of their business.

The contention that the saturant is of first importance is quite correct, but at the same time the final improved product will depend on both the saturant and the braid construction. To that end a better knowledge of braids and braiding construction should be important; a braiding schedule specifying the following: size of cotton; number of plys; number of ends; picks per inch to attain a so-called 100 per cent braid covering according to size or diameter of wire. The wording "closely woven braid" in present specifications is not very definite and lends itself readily to controversy. Again, in normal times, cotton is quite an item in the quoted price in comparison with the present saturant, although it may not be with a high quality saturant.

The statement of having "a more solid and homogeneous material next to the conductor" should also indicate that flexibility in the material is desirable. The product of the Peerless Wire and Cable Company at Pennington, N. J. may be somewhat along this line, also the experimental work done by the American Steel & Wire Co., Worcester, Mass., on a similar type of line wire, *viz.:* paper tape next to the conductor and a single cotton braid overall, weatherproofed with a high quality saturant, recorded in the paper.

The matter of using a high saturating temperature, 400 deg. fahr., with a high quality saturant should not act as an impediment, or be detrimental to the tensile strength of the cotton braid, provided proper precautions and refinements are used during the saturating process. Locomotive headlight wires for steam engines are saturated under conditions quite similar with good results. Standardization of this practise, high saturating temperatures, would undoubtedly mean revamping the present apparatus found in most wire plants.

It may be of interest to know that the railroads purchase large amounts of line wire, usually in accordance with A.R.A. specifications. These specifications require two cotton braids over the conductor, the conductor being either iron wire, copper, or copper alloy. This leads to the question as to why the utilities should require three braids, or their equivalent, for their purposes. True, the operating conditions, voltage for instance, are different, yet from contact with operating men it has been my impression that the utilities in replacing festooned line wire were not worried about the lowered insulating value, but to comply with municipal ordinances, or public opinion, or perhaps to establish an underground system. So from this why would not a similar wire be just as good, regardless of whether rural or urban use was contemplated.

C. F. Harding, L. L. Carter, J. W. Olson: Many reports are received of weatherproof wires that have been in service for periods of 15 to 35 years without shedding the braided covering. In marked contrast to this there are many reports of weatherproof wire coverings that have failed in periods as short as two years, particularly in hot climates. It should be remembered that the majority of the wires that have failed quickly have been produced in the last 10 or 12 years whereas the longer lived wires were produced in the years previous to 1920 or previous to the war period.

A graphic illustration of the differences in the weathering qualities of the recent product and the older weatherproof wire is the fact that certain commercial wires placed in the outdoor weathering exposure at Purdue in September of 1930 appear to be in poorer condition than wires installed in an outdoor weathering rack in Chicago in 1916.

BRIEF HISTORY OF WEATHERPROOF WIRE PRODUCTION METHODS

To explain the reasons for this variation in life and the reasons for the changes in weatherproof wire covering materials and production methods, which have caused this change in life, it seems desirable to give a brief history of weatherproof wire production methods and materials.

Before the start of the last decade, weatherproof wire coverings were usually built up of braids made from high strength, long fiber, cotton yarn, often saturated after each braid was applied and usually saturated with natural asphalts rather than petroleum base asphalts. Production methods were slow and the materials used more expensive than it is now possible to use.

With the start of the last decade the increased demand for electric service caused a very great increase in demand for weatherproof wire. Coupled with this demand for more wire was an insistence that the cost of the wire be lowered. The increased demand alone, if the earlier materials and production methods had been used, would probably have resulted in an increased cost of the product. We thus had two factors, namely, the increased demand and the demand for lower prices, that forced the substitution of cheaper materials and speedier production methods in the weatherproof wire industry.

The weatherproof wire producers began to use cheaper grades of cotton yarn and looser braids and they turned to petroleum by-product asphalts for saturants. They further changed from saturation of each braid after its application to the application of all three braids in one step and the saturation of these braids as a second step. To obtain the production speeds required and to saturate three braids in one step at the temperatures available in the wire plants (that of low pressure steam) the use of low melting point petroleum asphalts of low viscosity at saturating temperatures became general.

In this short description of the change on the industry we have the background for the short-lived weatherproof wire coverings produced in the past 10 or 12 years. This background of the changes in the weatherproof wire industry is of much importance to anyone interested in developing a longer lived covering.

FUNDAMENTAL PROBLEM INVOLVED IN RESEARCH AT PURDUE

The real problem in the research work at Purdue has been that of finding a material which could be used as a saturant, that would provide equal or better life than was had by the weatherproof wire coverings produced years ago but at a very slight increase over the present cost of production.

The answer to the question "if long lived wire coverings were produced 15 to 20 years ago, why cannot they readily be produced again" is very simple. Such coverings could not be produced with the old materials and the old methods at a price that could, in most cases be economically justified.

IMPROVEMENT IN WIRE COVERINGS CAN BE MADE AT LITTLE INCREASED COST

The use, as weatherproof wire saturants, of the air blown asphalts meeting the preliminary specification which has been developed, has been proven in the laboratory to yield a greatly increased length of life of the covering on any size wire, over that provided by the usual commercial saturants and to provide a greatly increased flexibility of the finished wire. The physical properties of these asphalts and the present commercial saturants are given in Table I. The preliminary specification follows:

> The saturating compound shall consist of a pure blown petroleum asphalt and shall not be mixed with any material such as paraffin, wax tailings or fluxes. It shall have the following physical properties:
>
> *Ball and Ring Fusing Point*: 180-200 deg. fahr.
>
> *Penetration*: 77 deg. fahr. 100 g., 5 sec. 35 or harder, tenths of mm.
>
> *Pliability*: A mold of the asphalt ¼ in. by 0.1 in. by 0.4 in. shall not break when subjected to an angle of bending of 15 deg. around a mandrel of 3/16 in. radius at a temperature of 0 deg. fahr. This test shall be made in the Reeve and Yeager pliability testing equipment, at a rate of bending of 10 deg. per minute.
>
> *Loss By Evaporation*: A 100 gram sample of the compound heated for 100 hr. at a temperature of 325 deg. fahr. shall not lose more than 1.0 g. in weight.
>
> *Rise in Fusing Point*: The difference in the ball and ring fusing point determined before and after the above heating test shall not be greater than 40 deg. fahr.
>
> *Change in Penetration After Heating*: The penetration of the sample subjected to the above heating test shall not become harder by more than 10 points. The crust formed on the sample during the heating test may be removed before determination of the penetration after heating.

Adequate proof of the improvement obtained by the use of these materials is given by comparing the wires in Fig. 1 with those in Fig. 2, all having had the same exposure in the accelerated weathering test. Fig. 1 shows the condition of wires saturated with the present commercial saturants after having been exposed in the accelerated weathering test at Purdue.

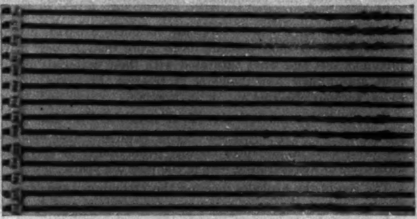

FIG. 1—CONDITION AFTER ACCELERATED WEATHERING TEST OF WIRES SATURATED WITH COMMERCIAL SOLVENTS

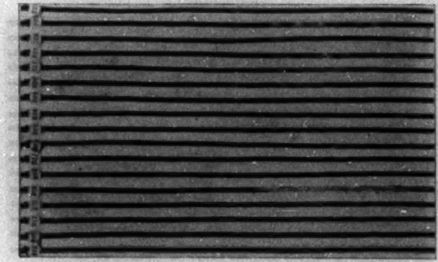

FIG. 2—CONDITION AFTER ACCELERATED WEATHERING TEST OF WIRES MEETING VARIOUS PARTS OF PRELIMINARY SPECIFICATIONS

Wires 815-8, 820-6, and 830 meet these specifications in every detail

The four wire coverings that have held up well on this test are saturated with very hard and brittle materials. The asphalts with which these four wires are saturated bend less than two degrees in the pliability test. This emphasizes the importance of applying both the laboratory pliability test and the accelerated weathering test in choosing the most satisfactory

TABLE I—COMPARISON OF PHYSICAL PROPERTIES, COMMERCIAL SATURANTS AND ASPHALTS PROPOSED AS SATURANTS

	Range of physical properties		Average of physical properties	
	Commercial saturants	Proposed saturants	Commercial saturants	Proposed saturants
B & R fusing point				
Before heating	119-158°F.	186-208°F.	143.2°F.	196.1°F.
After heating	176-245	209-232	198.4	220.7
Penetration: 77°F., 100 grams, 5 seconds				
Before heating	3-66	21-33	25.5	27.5
After heating				
With crust	0-23	0-4	8.7	1.0
Crust removed	0-26	17-29	11.8	22.3
Loss in weight during heating	0.12% gain, 7.17% loss	0.03-0.97% loss	1.63%	0.36%
Pliability	0.41° -13.3°	16.2°-48°	3.21°	26.5°
Specific gravity				
Before heating	1.001-1.200	0.987-1.044	1.071	1.011
After heating	1.021-1.208	0.988-1.042	1.080	1.013

weather resistant coverings. The wires in Fig. 2 have coverings saturated with air blown asphalts meeting the specification for melting point and penetration, but in the case of samples 819, 826, 827, 828, 829 and 831 not meeting other parts of the specification such as that for pliability or changes in physical properties with long continued heating. It may be readily seen that the wires meeting the preliminary specification, in every detail, provide a vast improvement in weather resistance over the commercial saturants. These wires are numbers 815-818, 820-826 and 830. All of these asphalts bend more than 15 deg. in the pliability test and wires saturated with these materials may be bent about their own diameter at freezing, or lower in some cases, without breaking any of the braids.

Sample 819 is saturated with a material that has shown peculiar breakdown when exposed to light and heat and that has been used in the lower melting point ranges in very great quantities of weatherproof wire in the past ten years.

The use of the asphalts meeting the preliminary specification requires only a change of saturating temperature and does provide a remarkable improvement in the weather resistance of the covering.

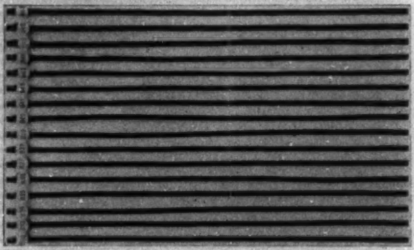

Fig. 3—Wires Illustrating the Improved Weather Resistance of Air

Blown asphalts to which proper inert mineral fillers have been added

Fig. 4 illustrates the smaller change in hardness of air blown asphalts as compared with the commercial saturants and also the greater stability at the higher operating temperatures. It may be seen that the air blown asphalts are harder, as an average, at temperatures of 60 deg. fahr. and higher, but are softer than the commercial saturants below this temperature.

Fig. 5 shows the smaller change in the hardness of the air blown asphalts as compared with the commercial saturants after being heated for 100 hours at 325 deg. fahr. It will be noted that the blown asphalts have not changed greatly while the commercial saturants have become much harder. This lack of change with long heating has been proven to correlate rather closely with the resistance of the wire covering to weathering.

Fig. 6 shows that higher temperatures are required to obtain saturation of the braided coverings with the air blown asphalts than are required in the case of the commercial saturants. Viscosities lower than 100 seconds per 100 revolutions are required to obtain saturation of triple braid coverings at present saturating speeds and temperatures of 360 deg. and higher are required for saturation with these asphalts.

These "air blown asphalts" are produced by blowing air through the heated petroleum residue, as compared to the production of the usual commercial saturant by blowing steam through the petroleum residue. Certain changes in the structure of the asphalt are produced by the air blowing which results in a much more stable asphalt of lower temperature susceptibility. The asphalts illustrated in Fig. 2 are stock products. They are not special materials in any sense. There is no reason to think that the increased use of air blown asphalts meeting these specifications should result in a marked increase in cost of the materials (which now cost very little more than the steam reduced asphalts) because the petroleum residue is just as readily blown to meet this specification as to meet one of a lower melting point.

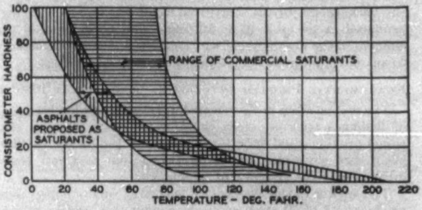

Fig. 4—Comparison of Initial Hardness

Commercial saturants and asphalts proposed as saturants

Modification of Asphalts

Fig. 3 shows the improvement that may be made in the weather resistance of the air blown asphalts by the use of the proper inert mineral filler. Wires numbers 832-835 are saturated with the same materials as wires 815-818 in Fig. 2 except that 30 per cent by weight of 325 mesh slate dust was added to the asphalt before saturation. Wires 840-842 in Fig. 4 are also asphalts to which certain modifying agents have been added. The use of such modifying materials provides an additional and very desirable improvement in the weather resistance of the wire covering and also may slightly reduce the cost of the saturant because of the cheapness of the slate dust. The use of the filler is particularly helpful in the case of the asphalt on the surface of the wire and in the case of the finishing materials.

Improved Finishing Materials

Finishing materials that are more flexible than the present waxes may be had and are much more desirable, particularly when some filler is used as a coating or an anti-stick in these finishes. Mica flake is particularly valuable as an outer finish both to prevent sticking and to improve weathering, reduce cracking, etc.

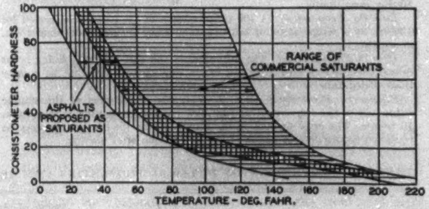

Fig. 5—Comparison of Hardness

Heated 100 hr. at 325 deg. fahr. Commercial saturants and asphalts proposed as saturants

Accelerated Weathering Test is Still Required in Choosing the Saturants and Finishers

While all of the asphalts which weather poorly in the wires in Fig. 2 would have been eliminated by requiring them to meet the preliminary specification, we cannot be certain as yet that this will always be true and we must still depend upon the accelerated weathering test to eliminate the poor materials. In the operation of the weather-ometer on the standard cycle used by the Bureau of Standards the commercial saturants all show extreme checking or cracking in only one day whereas the asphalts recommended show no signs of deterioration in this time, except in one instance, thus checking the tests of the asphalts in wires as illustrated in Figs. 1, 2, and 3.

Asphalt Analysis

The analysis of asphalt and the determination of chemical unsaturation are now being carried on to learn if it is possible to correlate some result of this analysis with the variation in weathering of the asphalts.

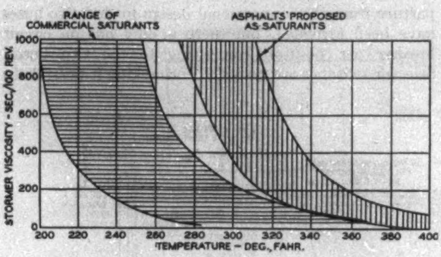

Fig. 6—Comparison of Viscosity

Commercial saturants and asphalts proposed as saturants

Additional Testing Equipment Designed or Constructed

The design for an improved Abraham consistometer and a Reeve & Yeager pliability test equipment especially adapted to this work has been completed. The rate of penetration in the consistometer and the rate of bending in the pliability tester will be quite constant as both are to be electrically driven and the degree of bending in the pliability test will be determined by automatic electric timing of the start and the finish of the bending period. The consistometer hardness will be read from a pressure gage which indicates the pressure on the table of the consistometer supporting the asphalt sample under test.

In the testing of finished wire a small electrically heated braid press and a pliability tester in which very small samples of asphalt may be tested have both been completed. The braid press is used to extract the saturant from the two inner braids of a finished wire. Sufficient asphalt is obtained from a two foot length of No. 6 wire for the standard ball and ring melt point test and the penetration determination. The pliability test can be made with this new equipment upon the small sample extracted from the braids.

The accelerated weathering equipment is still depended upon to indicate certain types of failures in the asphaltic saturant.

New and Improved Coverings

The much superior insulation of paper tape covered samples having a single weatherproofed outer braid has been shown repeatedly by the slower decrease in insulation resistance of this covering when immersed in water, as compared with the triple braid construction. The use of this paper tape and single braid covering provides a conductor of lighter weight and much smaller overall diameter, which means that sleet and wind loads will be lower, and also of consistently high dielectric strength even with considerable exposure of the braids to the weather.

Conclusion

This discussion is intended to answer the questions raised at the time of presenting this paper and also to summarize the work done since the writing of the original paper.

The work done since writing the paper has given ample proof that the materials recommended will provide longer life for weatherproof wire coverings and also that these materials may be obtained within a reasonable distance of any weatherproof wire plant in the United States.

It is felt that the experience and equipment built up at Purdue as a result of this work should prove of value in the development of improved weatherproof braids as applied to other types of wire than the ordinary weatherproof wire. This is especially apparent when it is pointed out that in looking for improved materials, the coverings of tree wires and other insulated overhead line wires were investigated to learn if the weatherproofing compounds used in the braids on these wires were superior to the ordinary weatherproofing compounds, and it was found that while these coverings were made of exceptionally strong and high grade braids they were not saturated with compounds in any way superior to the present commercial weatherproof saturants.

Electrical Design Features of Waukegan Station

BY E. C. WILLIAMS*
Member, A.I.E.E.

THE Waukegan Station of the Public Service Company of No. Illinois is located at the north limit of the city of Waukegan on the west shore of Lake Michigan. This steam generating station is the chief energy supply point between the Illinois-Wisconsin State line and Chicago. It also forms one of the supply points for the Company's 132-kv. transmission system which forms an outer belt around Chicago. The major substations and interconnections with other companies are shown in Fig. 1. The main one-line diagram of the station is presented in Fig. 2.

Some features of the design anticipated the general use of similar equipment in other stations. The general design of the station, however, paralleled the advance of the art, as the station has developed from a single 25,000-kw., 12,000-volt unit in 1923 to five units having a total capacity of 290,000 kw. in 1931. The fifth of these is a 115,000-kw. unit generating at 18,000 volts.

Waukegan Station is unique in a number of its design features, some of which result in a material capital saving, some in a greater safety to personnel, and others in greater operating reliability. Probably the best way of presenting these features is to review the development of the station in three fairly distinct periods.

INITIAL INSTALLATION

In the first period (units 1 and 2), a double 12-kv. bus was started using 15-kv. truck type oil circuit breakers and cell-type construction to enclose the buses, disconnecting switches, and instrument transformers, as well as the oil circuit breakers. A Cory lock system was provided to prevent improper operating sequence of the disconnecting switches. The auxiliary equipment operated at 480 volts, and an ordinary open bus was provided for this purpose. All cables were run in conduits from the single bus used for the turbine and boiler-room auxiliaries. Reserve for the auxiliaries was provided by a tie between the unit 1 and 2 sections of the auxiliary bus. Feeders were run from the 480-volt auxiliary bus to *VV* switch groups located at various load centers along the coal-preparation and conveying system.

METAL-CLAD SWITCHGEAR USED IN SECOND PERIOD

The second period started with the installation of a unit twice the size of the original one, and a radical departure from conventional design was introduced by the use of metal-clad switchgear for the 12,000-volt equipment, and for the 2,400-volt and 480-volt auxiliary equipment. Fig. 3 shows the 12,000-volt, type M switchgear.

The bus arrangement of the 12,000-volt metal-clad switchgear used for units 3 and 4 is somewhat of a departure from the conventional design in that two buses have been provided, but there is only one oil circuit breaker per position connecting to the two buses. Selector switches are provided for making it possible to place the oil switch on either the main or the reserve bus, as desired. There are fourteen of these units, which range in carrying capacity from 600 to 4,000 amperes. The interrupting capacity of all these switchgear units is 1,500,000 kva.

switches cannot be opened or closed unless the main oil circuit breaker is open. Also, the oil circuit breakers cannot be lifted from their tanks, nor can the selector and isolating switch tanks be lowered, when current carrying parts are alive.

AUXILIARY EQUIPMENT SIZE CAUSES OPERATING VOLTAGE CHANGE

The use of larger turbo-generator units required boilers of greater steaming capacity and larger auxiliary equipment. As a result of the increased size of auxiliary equipment, larger motors were used; so the operating voltage was changed from 480 to 2,400 volts for these motors. Also, the larger capacity of the boilers made it necessary to provide more flexible operation of the stoker-feed mechanism on the boilers of unit 3. To provide this flexibility, a-c. brush-shifting motors were used. This arrangement provides almost as much flexibility as could be obtained by the use of the customary d-c. motors and control.

UNIT 4 DESIGN FEATURES

Although the same general electrical design was used for unit 3 and 4 installations, there are a few features of the unit 4 installation that are of interest. Since unit 4 has a capacity of 65,000 kilowatts, the carrying capacity of its metal-clad switchgear increased; the size and number of auxiliary motors increased because of the use of larger auxiliaries and also because unit-type coal-pulverizing mills were installed. Centralized control of the boiler coal and air supply auxiliary motors was provided on panels similar to the one shown in Fig. 4; and the electrical control system was designed for either manual or automatic operation, in response to the demands of the automatic combustion-control equipment which regulates the coal and air supply for the boilers.

PROTECTION ON PULVERIZED FUEL SYSTEM

The use of automatic combustion-control equipment and of pulverized coal made it necessary to exercise unusual care in designing the control and protective system. By designing the system so that a negative pressure or suction must be present inside the furnace when it is in service, the possibility of the pulverized coal's igniting and flashing back into a pulverizing mill and causing an explosion, are eliminated. This is the principle followed in designing, for the boiler-feed auxiliary equipment, an electrical interlock system which prevents any deviation from the prescribed operating procedure.

STARTING SEQUENCE

The prescribed starting sequence of the equipment that must be followed whenever a boiler is fired up is as follows:

1. Start low-speed, induced-draft fan, wound-rotor motor. When the resistance is all out of the secondary circuit, the drum controller automatically closes the high-speed squirrel-cage motor oil switch.
2. When the induced draft fan is up to speed, the forced-draft fan oil switch can be closed.
3. After the forced-draft fan motor is up to speed, the exhauster-fan motor can be started, and this can be followed, in order, by the pulverizing mills and the coal feeders.

Method of Making Prescribed Operating Sequence Effective. Each fan, exhauster, pulverizing mill, etc., has its own oil switch, and the closing and trip circuits of these oil switches are so interconnected that it is impossible for an operator to close an oil switch unless the equipment ahead of it in the sequence is running; that is, if an operator attempts to run a pulverizing-mill motor before placing the draft fans and the exhauster fan in service, the oil circuit breaker controlling the pulverizing-mill motor cannot be closed.

FIG. 3—12,000-VOLT, TYPE M, METAL-CLAD SWITCHGEAR

TWO-MOTOR DRIVE FOR INDUCED-DRAFT FANS

To provide the maximum operating flexibility and reliability, two motors are used on each induced-draft fan. The fan starts on the low-speed wound rotor motor; after it is up to its maximum speed, the drum controller completes a circuit which closes the high-speed motor oil switch and trips out the low-speed motor oil switch. If the high-speed motor should fail to start or fail in service, the operation of the overload relays would function to place the low-speed motor in service. If the low-speed motor should fail, the protective relay operation would cause the high-speed motor oil circuit breaker to close. This arrangement, of course, complicates the interlock scheme, but this problem was met by using centrifugal switches on the motor shafts to complete or open auxiliary switch circuits on the oil switches as the motor speed increases or decreases.

UNIT 5 INSTALLATION CONSTITUTES THIRD PERIOD OF DEVELOPMENT

In the third period, the unit illustrated in Fig. 5, which is over four times the capacity of the original 25,000-kw. unit, was placed in service. Since the greater part of the output of this unit is transmitted at 132,000 volts, it was decided to omit the generator bus and arrange for switching at the transmission voltage. This decision permitted the use of any convenient generating voltage, and the manufacturer selected 18,000 volts as the most feasible from the manufacturing standpoint. Subsequent units, of course, may generate at other voltages. As the generator and its associated 120,000-kva. transformer bank constitute an operating unit with no intervening bus, the generator leads had to be tapped to supply the 10,000-kva. auxiliary transformer. The high-voltage and low-voltage switchgear units provided for this transformer are

FIG. 5—115,000-KW., 18,000-VOLT GENERATOR 5

tripped by differential relays in case internal trouble develops. In this way, interference with the operation of the generator is avoided.

Auxiliary System

The low side of this 10,000-kva., 18,000/2,400-volt transformer is connected to the main 2,400-volt station auxiliary bus. This bus can be sectionalized by units if desired, or it can be operated as one bus. Reactors have been provided between sections of the auxiliary bus for fault current control. Power for starting the auxiliaries on units 3, 4, or 5, or for emergency operation in case one of the station auxiliary transformers is out of service, is obtained from the station auxiliary bus. Fig. 6 gives a one-line diagram of the station auxiliary system.

The present auxiliary power installation provides 9.4 per cent of the generator capacity in auxiliary transformers. The active and reserve transformer capacities are 7.4 per cent and 2 per cent respectively. These transformer capacities have been selected so that we have 20 to 30 per cent unused capacity in each transformer under normal demand conditions. This normally unused capacity provides:

1. For equipment not included in the original design but which appears desirable to install later.
2. A reduction of the investment in reserve transformers, thus saving foundations, switching and control equipment, and installation costs for an "unproductive" transformer.
3. The excess capacity required for station overloads.

The general arrangement, design, and type of auxiliary switchgear used for units 1 and 2 and for the succeeding three units offers quite a contrast, as well as showing the development of the art. The auxiliary system used for units 1 and 2 was of an open-bus type with its connections extending from the oil switches up to the disconnecting switches and then to the overhead bus, and considerable space was occupied for a comparatively small number of pieces of auxiliary equipment. All of the switching equipment for the turbine and the boiler-room was supplied from a single bus in the switch-house. On the other hand, for units 3, 4, and 5, 2,400-volt metal-clad switchgear has been used for the main auxiliaries, and separate buses have been provided for the equipment in the turbine-room and in the boiler-room. Two feeders are provided from the main bus

over to the boiler-room auxiliary bus. These feeders are protected differentially, and the bus in the boiler-room, as well as the main bus in the switch-house basement, can be sectionalized.

Generator Field Control

Another point in which the change in practise is apparent is in the method of controlling the generator field. Instead of using generator field rheostats, as had been done for the preceding four units, a main and a pilot exciter have been provided on the shaft of generator 5. The exciters and the generator field are so interconnected that variations of the main exciter field rheostat provide the means of controlling the generator voltage. This arrangement results in a considerable saving due to the fact that there are no generator field rheostat losses; in addition, a much more rapid and flexible method of controlling the generator is provided. In case automatic voltage control is considered advisable, this feature can very easily be provided at a comparatively small additional cost.

Excitation. All the generator field exciters, except on unit 5, are connected to a common excitation bus. As all these exciters have excess capacity, this design provides reserve for any of the exciters on the first four generators. Consideration of the facts, however, that generator 5 must be stopped to repair either exciter, because of their locations; that the main exciter will operate self-excited, thus making it possible to operate without the pilot exciter, and also the reliability of present day exciters, led to the conclusion that the expense of reserve excitation was unjustified.

Instrument Transformers. One of the features of the generator installation for which it has always been rather awkward to make a satisfactory design is the instrument-transformer installation for metering and protective purposes. On the first four units installed, the current and potential transformers have been installed in the generator foundations in rather inaccessible places, or in rather unsightly and inaccessible transite enclosures on the side of the generator foundations. On the unit 5 installation, however, an extension of the metal-clad switchgear idea was made. The metering and protective transformers were placed in metal-clad petrolatum-filled compartments in a recess in the side of the generator foundation in such a way as to make a safe, compact, accessible, and well-appearing installation. The metal-clad instrument-transformer compartments were designed with potheads on the lower side ready for the installation of the generator cables.

Generator Cable and Pothead Installations and Insulation

On the unit 5 installation four single-conductor, 3,000,000-circular mil, paper-core, 25-kv. paper-insulated, lead-covered cables are used for each phase. These cables extend from the generator to the 120,000-kva. transformer bank, in fiber ducts. This 16-duct bank was designed in the form of a square surrounding a large, square tile placed in the center of the duct bank to permit air circulation thus equalizing the internal and external temperatures of the ducts.

Special care in design was used to make the cables carry equal load currents and to avoid injurious sheath voltages. The cable phases in the duct have been so arranged that the electromagnetic fields surrounding the cables tend to neutralize each other, thus equalizing reactances and avoiding reductions in carrying capacity.

As it was considered more economical to have induced voltages on the cable sheaths than to suffer the losses due to induced sheath currents, cable-sheath insulators were placed at the ends and at about the midpoint of the 550-ft. fiber-duct run, thus dividing the cable sheaths into two sections. These two cable-sheath sections are grounded at their midpoints, thus making the induced sheath voltage too small to affect the lead-cable sheaths injuriously.

On the other generator installations, short cable runs have been installed between the generators and the oil circuit breakers connecting to the 12-kv. station bus. On unit 4, for instance, this run is installed mainly in the open air in split aluminum tubing suspended from the turbine-room floor. Since conditions were somewhat different for the preceding three units, an ordinary fiber-duct and concrete cable run was used.

As an added safety factor, 17,000-volt insulation on the cable has been used for the units which operate at 12,000 volts between phases, or 6,900 volts to ground. On unit 5, which operates at 18,000 volts or approximately 11,000 volts to ground, 25-kv. insulation has been provided on the cable. Not only has higher insulation than required for rated voltage been used, but very liberal conductor areas have been provided also. On all the 12,000-volt cables, compound-filled potheads were used. On the 18,000-volt unit 5 installation, oil-filled potheads, as well as oil-filled joints, have been used as an added safety factor which should insure maximum reliability in service.

Small Power Cable. As a result of the development of various types of armored cable which have proved quite satisfactory in service, it has been possible to eliminate the very expensive conduit runs which were needed to protect cable of the ordinary type from mechanical injury. Instead, troughs suspended from the ceiling are provided. The armored cables are laid in these troughs much more quickly than cable could be pulled through conduit. As a result of this change in practise, the cost of our cable installations has been materially reduced because of the saving in drafting-room and field work.

Protective Relays

Various types of relays have been used to protect tne equipment. The generators, cables, and transformers are protected with differential relays. The transformers are also equipped with overcurrent-relay protection. Some of the motors are equipped with phase-balancing relay protection and others with overcurrent protection, depending on the particular duty. The 132-kv. line protection consists of impedance relays which operate in conjunction with overcurrent and undervoltage auxiliary relays. This arrangement makes it unnecessary to change current-transformer ratios in light or heavy-load periods.

OUTDOOR INSTALLATIONS

The outdoor installations at Waukegan have gone through two successive stages of design similar to those involving the indoor equipment. At the time unit 1 was installed, it supplied a 25,000-kva. 12/33-kv. transformer bank, and an open-type main and transfer-bus switching structure. At this time, also, the first 132,000-volt installation was made. This consisted of a 30,000-kva. water-cooled transformer bank provided with an air-break switch only, on the high-voltage side. The associated transmission line extended about 28 miles to a step-down substation.

The second stage occurred in 1927 as a result of the installation of the second 132-kv. line. This necessitated the 132-kv. switching structure and bus, which was installed in conjunction with this unit. At this time, a 60,000-kva. water-cooled transformer equipped with load-ratio control was installed. The steel switching structure was added to as additional lines were needed, and for unit 4, a 60,000-kva. oil air-cooled transformer bank was installed. This bank is also equipped with load-ratio control equipment.

132-KV. SWITCHING STRUCTURE

The 132,000-volt structure has a number of rather unusual features. To conserve space in a north-and-south direction, it was necessary to use more in an east-and-west direction. This permitted placing the equipment for a line and a transformer in a bay 38 ft. 6 in. long from north to south, but much wider than this from east to west. As the main bus is located above the other equipment in the middle of the structure, the structure appears to have three buses. The line and transformer buses, however, are connected so that they form a rectangular "ring" bus with the main bus in the middle. The line and transformer or reserve bus may be sectionalized by means of an oil switch, or by means of load-break disconnecting switches.

132-KV. METAL-CLAD SWITCHGEAR

The first 132,000-volt switchgear ever used has been placed in service as part of the unit 5 installation. Two double bus units were installed as shown in Fig. 7, one for switching the high-voltage side of the 120,000-kva. transformer bank supplied by generator 5, and one for an additional 132,000-volt transmission line. The buses of these two units are connected to, and form an extension of, the main and reserve buses in the open-type steel structure. These two double bus switchgear units are arranged as indicated in Fig. 8, and consist of oil-filled cable buses and interconnections, special motor-driven disconnecting switches enclosed in metal housings, oil switches equipped with potheads instead of outdoor bushings, and special bus connections and disconnecting devices for the instrument transformers.

As this switchgear is the first of its kind, the details of its capacity and design features are of interest. The switchgear is rated to carry 1,200 amperes and the oil circuit breakers will interrupt 2,500,000-kva. at rated voltage. The capacity of the buses may be increased to 2,400 amperes by installing another set of buses. The present buses consist of 3,020,000-cir. mil., oil-filled, paper-insulated, lead-covered, copper-armored cable. Isolated racks support the bus cable about nine feet above the switchgear foundations as it loops from switchgear unit to switchgear unit. The ends of each of these bus cable loops are insulated, and the midpoint of each cable sheath in each loop is grounded to keep the induced voltage in the cable sheath at a minimum.

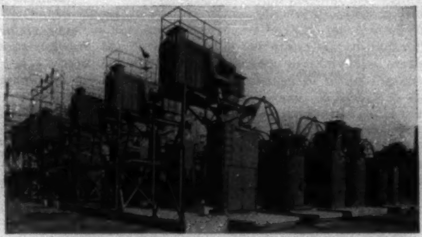

FIG. 7—THE 132-KV. METAL-CLAD SWITCHGEAR AT WAUKEGAN

The disconnecting switch consists of contacts in an oil-filled tank equipped with entrance bushings which are, in turn, enclosed in an outer housing. The tank, as well as the bushing on the bus side, is raised and lowered by a motor-driven mechanism, and overtravel is prevented by limit switches. When the tank is lowered, the circuit is opened under oil and the bus contact on the entrance bushing withdraws from its bus receptacle, thus providing a visual separation, which may be observed from the outside of the housing through a sight glass. The bus receptacle consists of a hollow porcelain shell that forms a part of the main structure into which the entrance bushing on the disconnecting switch tank enters. The opening in the lower end of this porcelain shell is automatically covered by a metal cover when the disconnecting switch is withdrawn. These switches are operated in groups from the oil circuit breaker control panel, or individually at the disconnecting unit.

As it is seldom necessary to disconnect a potential transformer, this disconnecting device is not motor operated. A portable motor has been provided, however, for raising or lowering the potential transformer "coupler" tank whenever necessary.

132-Kv. Switchgear Safety Features. There is a number of interlocks provided to prevent operating errors and to protect personnel. For instance, one of the interlocks prevents opening the upper door in the disconnecting switch house until the disconnecting switch is opened, which causes the shutter preventing access to live parts to close. Another interlock prevents operation of any or all disconnecting switches on both sides of the breaker unless the breaker is open. This interlock is effective on each disconnecting switch on individual operation, as well as on group control. The breaker cannot be closed unless all the disconnecting switches on both sides of the breaker are fully open or completely closed. An interlock also prevents operating any of the line disconnecting switches unless the line cable test switches are open. Conversely, no line cable test switch can be operated until line disconnecting switches have been opened. An interlock also prevents the lowering of any potential transformer coupler tank unless the ground switch and test switch on that phase are closed. An interlock prevents opening any ground switch or test switch until the potential transformer coupler tank is in the connected position. This is accomplished by means of a system of Cory locks.

A-C. Car-Mule Drive

One of the recent additions to the coal-handling system at this station is the coal-car mule, which pushes the loaded cars up an incline to the rotary car dumper. The special service requirements of the car-mule drive would normally dictate the use of d-c. motors, but, as direct current has not been necessary for the other auxiliaries, except for control purposes, it was decided to avoid its use for this device, if possible. Accordingly an a-c. system was developed which is, perhaps, the first of its type used in this country. Solution of the problems of securing large variations in torque with large variations in speed, of obtaining a flexible control system, and of taking the slack out of the hoisting cable to prevent breakage when the load is suddenly applied, have made the use of a-c. motors possible.

The essential feature of this installation is the use of a slow, two-speed, 440-volt, high-torque motor. Coupled directly to the torque motor is the 500-hp., 2,300-volt, wound-rotor, main driving motor. The drive shaft to which the motors are coupled is geared to the car-mule cable-hoisting and lowering drum.

The control system of the equipment which pushes a loaded coal car up the incline is complex, but to hoist a car automatically, it is only necessary for the operator to move a master control switch to the final point. This closes contactors which put the torque motor on its high-speed winding and thus bring the car mule out of the pit at a speed of 150 ft. per minute. As the car mule approaches the coal-car which has rolled over the hump, a limit switch operates and energizes intermediate circuits that put the torque motor on its low-speed winding, so that the mule engages the coal-car at a speed of 50 ft. per minute. This operation also places the main motor on the line with all its starting resistance inserted. After the car has been picked up, another limit switch operates to energize a contactor which accelerates the main motor. This process continues in six steps until the main motor reaches its maximum speed of about 300 ft. per minute. As the car approaches the car-dumper cradle, the car is slowed down to 150 ft. per minute by inserting automatically all of the main motor resistance, and the torque motor is put on its high-speed winding. If the cradle is properly seated, the car and mule will proceed to the final mule limit; at this point the motors stop automatically and the brakes set. By reversal of the master switch the motors operating the track gates, through which the car mule leaves or enters the pit, change the position of the gates and the car mule is lowered automatically.

Discussion

A. H. Lovell: To one who is not a resident of this territory of Chicago and its adjacent western surroundings, it is very puzzling that Waukegan, built for heavy energy production, in relation to the Chicago load, should have chosen units of only 25,000 kw. in 1923 and 65,000 kw. in 1930. Will the author discuss this in relation to the size of the load in Chicago at those times?

W. S. Monroe: The history of the Waukegan power station from the time the first unit was ordered in 1921, represented, in a large measure, the development of the power station industry in the Chicago District so far as steam pressure and steam temperature are concerned, and the change of boiler furnaces from the chain grate stoker to pulverized coal. Referring to the size of the units, the first two represented the largest units that it seemed desirable to put into the station, considering the load available in the district, and the last three units, Nos. 3, 4 and 5, of 60,000, 75,000 and 105,000 kw. respectively, were each the largest single shaft unit available at the time they were ordered.

115,000-Kw. Turbo-Alternator

BY R. B. WILLIAMSON*

Fellow, A.I.E.E.

Synopsis.—*Due to the increasing use of large single-shaft steam turbine units, it has been necessary to design very large generators operating at 1,800 r.p.m. The present paper describes a 115,000-kw. unit recently placed in operation. The generator is wound for 18,000 volts and the whole output of the machine, with the exception of a small part used for the operation of auxiliaries, is stepped up to 132 kv. and all switching is done on the high-voltage side of the transformers. It was possible, therefore, to design the generator for a voltage that would permit a simple two-conductor per slot winding.*

On account of the great axial length of the machine, ventilation required careful study and a new scheme of rotor ventilation was developed to secure uniform cooling throughout the length of the long rotor body. The stator ventilation is of the inward-outward parallel flow type with fourteen parallel paths in each half of the stator.

Air circulation is provided by four single inlet motor-driven blowers mounted under the generator. A fin type radiator cooler is mounted under the generator yoke and condensate is circulated through the cooler. Excitation is furnished from a 350-kw., 250-volt coupled, shunt-wound exciter and a 7½-kw. overhung pilot exciter is used to excite the fields of the main exciter.

THE development of large turbo-alternators has in recent years been characterized by the great increase in size of machines for operation at 1,800 r.p.m. The later designs of large steam turbines tend toward single shaft units and consequently the generator has to be large enough to carry the full output of the steam turbine. With units of the compound or triple-expansion type, the total output was divided between two or three generators and the maximum size of generator required was considerably smaller than with single shaft units. There has, therefore, been a demand for very large generators operating at 1,800 r.p.m. and the designer has had to solve a number of problems, mechanical and electrical, because of the great axial length of these machines and the large weights involved, particularly in the rotor.

FIG. 1—115,000-KW. UNIT INSTALLED

Following is a description of a 115,000-kw., 0.95-power factor, 121,000-kva., 1,800-r.p.m. generator put into operation in September, 1931, in the Waukegan Station of the Public Service Company of Northern Illinois. This generator is wound for 18,000 volts, 3,884 amperes, three-phase, 60 cycles. A general view of the unit as installed in the station is shown in Fig. 1.

STATOR CONSTRUCTION

The stator frame is of welded construction and made in two sections for convenience in handling, the halves being bolted together in a plane, normal to the shaft, at the center of the machine. Fig. 2 shows an end view of the stator core and yoke with the stator laminations in place, and Fig. 3 shows the completed winding. The axial length of the laminated core is 281 in. (714 cm.) between end heads. The punchings are clamped between heavy finger plates of non-magnetic cast steel. In stacking the core, the laminations were pressed down, by means of hydraulic jacks, as the work progressed. The core punchings are of silicon steel having a loss not to exceed 0.75 watt per lb., at a density of 10,000 c.g.s. lines per sq. cm., 60 cycles. A sectional view of the generator is shown in Fig. 4.

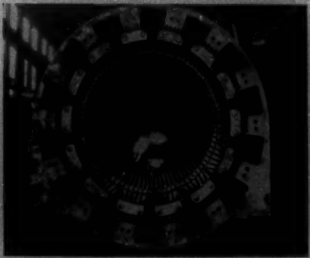

FIG. 2—END VIEW OF STATOR WITH LAMINATIONS IN PLACE

The stator winding is placed in 84 open slots, 21 per pole, and connected in two parallel circuits. In selecting the voltage for this generator, 18,000 volts was decided on after careful study, both from the operating point of view and from considerations of generator design. The whole output of the machine with the exception of a small part used for the operation of station auxiliaries, is stepped up and all switching done on the

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

high-voltage side of the transformers, hence the voltage of this unit did not have to correspond with that of the older units in the station, and it was possible to wind the generator for 18,000 volts in order to obtain the best type of stator winding. Two conductors per slot give the simplest form of winding and eliminate practically all danger of insulation breakdown between turns. The coils are made in halves, each conductor being built up of asbestos-covered, varnish-treated strands transposed to eliminate stray currents. The half coils are connected together at each end of the stator with solid clips, to form one-turn coils. Since the winding is in two parallel circuits, each conductor carries one-half of the total current output.

Fig. 3—Stator with Completed Winding

The coils are insulated with mica tape, with asphaltum base binder. The insulation is molded in place in such manner as to secure a dense insulation free from air inclusions. A layer of asbestos tape treated with varnish is placed on the outside of the coils to form a corona sheath. The whole winding was subjected to the standard A.I.E.E. test of 37,000 volts for one minute and there was very little evidence of corona at this voltage. Fig. 5 shows the stator slot and arrangement of conductors. The projecting ends of the coils, Fig. 6, are supported by lashing to insulated, non-magnetic brackets which form ring supports and at the same time avoid closed circuits for stray currents induced by leakage fluxes.

The terminals of the winding are brought out at each side of the end housing so as not to interfere with the air ducts, and also to render them accessible above the floor line of the unit. Line terminals are brought out on one side and neutrals on the other.

Fig. 7 shows the arrangement of the special compound filled terminal boxes on the line side of the generator. These are mounted on the foundation wall directly below the outlet on the generator. Each of the leads is provided with a terminal box in which current transformers for differential protection are mounted. A tap for auxiliary power supply is taken off directly from the main leads as indicated, and a current transformer in the

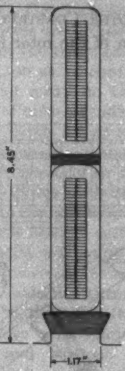

Fig. 5—Stator Slot Section Showing Conductor Arrangement

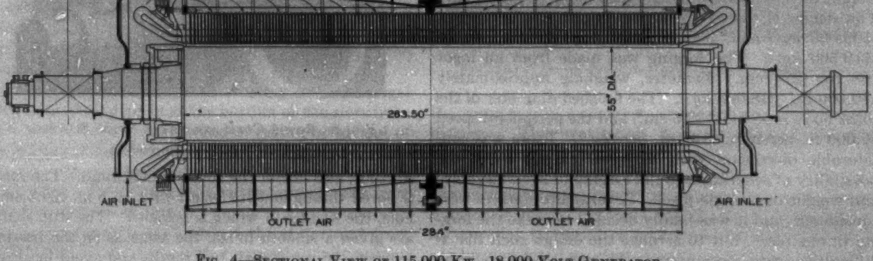

Fig. 4—Sectional View of 115,000-Kw., 18,000-Volt Generator

auxiliary tap is provided in the terminal box together with potential transformers for the machine. The whole arrangement is compact and affords a high degree of insulation. The boxes are filled with soft compound and the potential transformers are oil-insulated. The cable potheads on the terminal boxes are oil-filled, and lead-covered cables are carried down the side wall of the foundation and protected by a casing extending to the basement floor. This casing is made of aluminum plates bolted together so as to be readily removable. The stator end enclosures are of non-magnetic cast iron. The stator with core and windings complete weighs 350,800 lb. net, (159,000 kg.) and was shipped on a special car designed for 400,000 lb. (181,000 kg.) load.

ROTOR CONSTRUCTION

The construction of the rotor for such a large high-speed machine, required a great deal of study as the weight of the finished rotor is 228,650 lb. (103,600 kg.). The weight of the rough turned forging was 240,000 lb. (109,000 kg.) and, before rough turning, 264,000 lb. (119,500 kg.). The forging was made from an ingot 108 in. (274 cm.) diameter, weighing approximately 480,000 lb. (218,000 kg.). The finished diameter of the rotor body is 55 in. (139.6 cm.) and the peripheral speed 26,000 ft. per min. (132 m. per sec.). There was considerable discussion with the steel makers as to the possibility of securing a sound forging of such large size and weight in a single piece. Several alternatives were considered, and it was finally decided to make the forging in one piece, but to arrange the design such that if difficulties were encountered, the stub-shafts could be cut off and stubs bolted to the body, thus making a three-piece construction. Fortunately, this was not necessary as the steel maker produced a single-piece forging which, after careful physical tests and inspection by boring, proved satisfactory in every respect.

FIG. 7—TERMINAL BOXES FOR STATOR LEADS

The material in the rotor forging is open hearth, carbon steel, with a small percentage of vanadium, thoroughly annealed. The body is approximately 24 ft. (732 cm.) long and the distance between bearing centers 420 in. (1,070 cm.). Fig. 8 shows the rotor body after slotting; also one of the coil retaining rings. The rotor is bored throughout its length with an 8 in. (20.3 cm.) hole, the surface of which is polished. The stub shafts are given a smooth finish, the same as on the bearing journals, to remove all tool marks and avoid localized

FIG. 8—ROTOR CORE AND SHAFT AFTER SLOTTING

stresses that might start cracks during long-continued service. For the same reason, all fillets on the rotor and end rings are carefully polished. The rotor end rings are of high tensile strength, non-magnetic alloy steel in order to reduce stray loss.

In general, the rotor construction does not differ materially from that used for similar large rotors. All insulation is of mica and asbestos. On account of the large diameter of the stub shafts it was not advisable to mount the collector rings between the outboard bearing and the generator, as the rings would have to be of such large diameter that the rubbing speed at the brushes would be too high. The rings were, therefore, mounted outside the bearing and leads brought through the shaft.

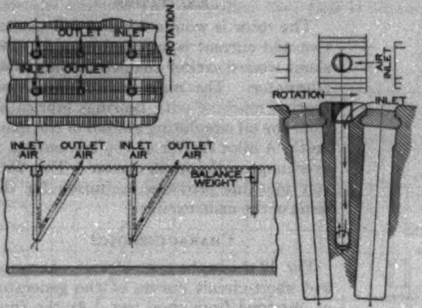

FIG. 9—METHOD OF ROTOR VENTILATION

A new method of ventilation was used on this rotor because, on account of its great axial length, the methods heretofore used would not be effective in ventilating the central part. The usual method of rotor ventilation has been to provide longitudinal channels under the coils, into which air can be drawn from each end of the rotor. Holes drilled down through the teeth connect with these channels and when the machine is in operation, air is drawn in from each end through the channels under the rotor coils and thrown out of the holes by centrifugal action. This method works well for rotors of medium length, but for very long machines it is difficult to secure enough inlet duct area under the coils to supply adequate ventilation, and what ventilation is obtained is not uniform along the length of the rotor body.

In the present case, instead of using the centrifugal effect and feeding air in at the bottom of the slots from each end, a method was devised of taking up air out of the air gap at the circumference of the rotor and utilizing the impact head to force air down through the ventilating holes and return it to the air gap. Air from separate ventilating fans is supplied under pressure to the air chambers at each end of the stator and from there passes into 14 inlets (Fig. 3) spaced equally around the back of the stator punchings. From these chambers it blows inward in a radial direction against the rotor, makes a U-turn and passes out radially through the yoke. Thus, air is blown in against the rotor at 14 points and this air is comparatively cool, as it has traveled only a short distance from the inlet. A small portion of the air is by-passed back of the coils in order to cool the part of the stator core behind the teeth, but the greater part blows in against the rotor. There is thus a strong circulation of air through the air gap at all points throughout the length of the rotor.

The scrubbing action of the surface and the ventilation at the ends of the rotor removes a large part of the heat, but it is also necessary to provide additional ventilation as stated above. Fig. 9 shows the method used in this case. Radial holes are drilled to within a short distance of the roots of the teeth and holes are drilled at an angle as shown, so as to connect with holes at the bottom. Plugs cut away on the under side are screwed into the tops of holes as indicated, and a short channel is cut in the tooth lip as shown, to connect with the slot in the under side of the plug. The plugs are of course locked in position so as to prevent any possibility of turning. When the rotor is rotating, at a peripheral speed in this case of 26,000 ft. per min. (132 m. per sec.) the impact head is sufficient to force air down through the radial holes and out through the holes at an angle. Numerous tests made on models, showed that the air velocity through the ventilating holes is at least 6,000-8,000 ft. per min. (30.5-40.7 m. per sec.). Also tests made with an experimental rotor, with and without these ventilating holes, showed a decided gain in cooling effect with the rotor run in a machine under exactly similar conditions. The ventilation does not depend on any centrifugal action, as the centrifugal effects on the air in the inlet and outlet holes are balanced. With this arrangement, as the length of the rotor is increased, the number of ventilating units and the air carrying capacity are also increased in proportion, and a long rotor can be ventilated as effectively as a short one. It might

FIG. 10—TWO OF THE FOUR MOTOR-DRIVEN BLOWERS

be thought that this method of rotor ventilation would be noisy, but such has not proved to be the case as the rotor makes no more noise than one provided with the usual centrifugal ventilation.

AIR SUPPLY

Air is supplied to the generator by four separate motor-driven blowers mounted within the foundation space, directly beneath the generator and operating on a closed system. Fig. 10 shows two of the blowers as installed, the other two being similarly located on the opposite side of the foundation. Separate fans were used for several reasons. With a rotor of such large weight and length of body, it was necessary to keep the stub shafts as short as possible and the use of self-contained fans with their air inlets adds considerably to the length of the shaft. Moreover, the large shaft restricts the air inlets to such an extent that self-contained fans could not deliver the amount of air required, without excessive inlet velocities and consequent loss in efficiency. Separate fans are more efficient and permit better mechanical design of the rotor, besides being more quiet in operation. Each fan can deliver 50,000 cu. ft. (1,420 cu. m.) of air per minute against 9 in. (22.8 cu. m.) static pressure. The fans operate at 1,160 r.p.m. and each requires a maximum of 104 hp. To allow ample margin, 150 hp. line-start, squirrel cage motors are provided. The fans are single inlet type with runners mounted directly on a shaft extension of the motor. All four fan inlets open directly into the chamber under the coolers into which the air is discharged. With the generator delivering 70,000-80,000 kw. it is found that two fans furnish sufficient air, and four are operated only under full load conditions. Outlet dampers are provided on each fan so that it can be cut off when not in use. Fig. 11 shows the general arrangement of the blowers in relation to the generator and air coolers.

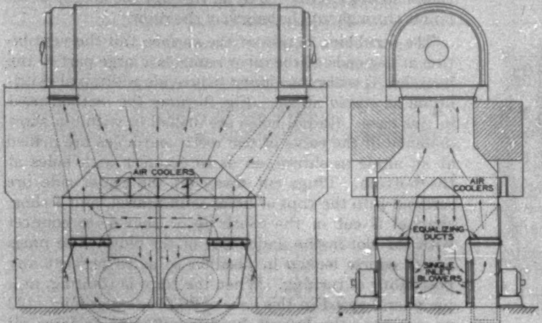

FIG. 11—GENERAL ARRANGEMENT OF MOTOR-DRIVEN BLOWERS

For cooling the air, condensate is circulated through a fin type radiator cooler mounted directly under the generator. The cooler is designed to handle 200,000 cu. ft. (5,670 cu. m.) of air per minute with a pressure drop not exceeding 1½ in. (3.81 cm.) water. With cooling water temperature not exceeding 80 deg. fahr. (26.6 deg. cent.), it will absorb 6,985,000 B.t.u. per hour and deliver air to the generator inlets at a temperature not exceeding 104 deg. fahr. (40 deg. cent.).

EXCITATION

The rotor is wound for 250-volt excitation and current is supplied by a 350-kw. shunt wound exciter coupled to the turbo-alternator. The main exciter is a two-bearing machine with bearings lubricated from the oil circulating system of the main unit. A pilot exciter of 7½ kw. output is overhung on the main exciter. This 250-volt machine provides excitation for the fields of the main exciter.

CHARACTERISTICS

Fig. 12 shows the open-circuit saturation and short-circuit curves of the generator as obtained from shop test. At the time of preparing this paper, complete tests for efficiency, heating, etc., had not been made, but regular operation on the station load indicates that the temperature rise of the generator at full load is well within the guarantees of 60 deg. cent. rise by detector on the stator, and 85 deg. cent. rise by resistance on the rotor. The estimated efficiency of the generator at rated load, including power required to drive the separate fans is 98.1 per cent.

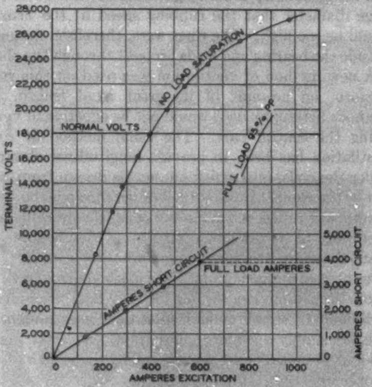

FIG. 12—OPEN-CIRCUIT SATURATION AND SHORT-CIRCUIT CHARACTERISTICS

Discussion

S. H. Mortensen: If in the design of a machine of the size described in the paper the effect of vibrations, stray fields, heating, etc., could be forgotten it should be possible to determine its most economical all around design from a careful analysis of the relative cost of labor and material involved, combined with the operating cost per kilowatt after installation. From such an analysis the corresponding generator efficiency could then be derived to serve as a guide for the design.

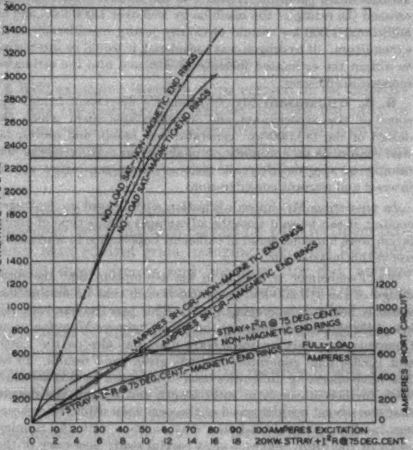

Fig. 1—No-Load Saturation and Synchronous Impedance Curves and Stray Loss

On a 2,500-kva. turbo-generator tested with magnetic and also non-magnetic coil support rings

However, vibrations, stray fields, heating, etc., if forgotten are apt to become exceedingly real and furthermore as present day tendencies combined with competition have made it necessary to give efficiency guarantees which approach those of transformers, it becomes incumbent on the designer to combine his best skill with that of the best material available for the generator construction. For the machine in question this has resulted in the use of silicon core steel and non-magnetic material wherever practicable. The use of silicon steel which is brittle when cold, makes it necessary to omit sharp corners from slots and dovetails and to provide core clamping devices which eliminate the danger of vibrations and loose core iron. Fig. 2 of the paper shows that this machine has sectionalized core clamping plates. As each section only covers 1/14 of the circumference they can be pulled up independently and compensate for variations in core length. To reduce stray losses the clamping plates and the spacers on the teeth of the center ventilating segments are made from non-magnetic material as are also the stator end covers. To further reduce stray fields and losses the material in the stator coil support rings is steel rendered non-magnetic by alloying it with manganese, nickel and chromium. On physical tests, this material had an ultimate strength of 135,000 lb. per sq. inch, a yield point of 92,000 lb. with an elastic limit of 56,000 lb. Its reduction in area was 42 per cent and the elongation 36 per cent. The effect of substituting non-magnetic for magnetic coil support rings on the leakage fields and stray losses of a 2,500-kva., 3,600-r.p.m. generator is depicted in Fig. 1. The respective curves show that fewer field ampere turns are required to generate a given voltage or short-circuit current with non-magnetic rings, which, interpreted in kva. means a larger output for a given rotor heating. In addition, the short-circuit losses with non-magnetic rings were only 58 per cent of those corresponding to magnetic rings. This, of course, means a decrease in the operating cost which, under circumstances may justify the increased first cost inherent to the use of the more expensive non-magnetic material in the support rings.

In connection with the operating voltage of the 115,000-kw. machine it is of interest to note that it was chosen so 1-turn coils could be used in its armature windings. It would seem that in installations where generator and step-up transformers can be considered as a unit the value of the generator voltage should be chosen to give the most favorable generator design, irrespective of voltage standards.

Prior to adopting the rotor ventilating scheme proposed by Mr. Williamson and shown in Fig. 9, a number of tests was made on models and also on a 4,500-kva. machine without and with the impact ventilating holes. The respective tests showed the new scheme to give better cooling than obtained with any of the schemes previously used, such as ventilating ducts in the rotor body, axial ducts under the rotor coils, axial slots in the pole center, etc., combined with the grooving of the rotor surface which Mr. Williamson introduced prior to 1911, to increase heat radiation from turbo-rotors. Curve *A*, Fig. 2 shows the rotor heating before, and curve *B* the results obtained after the surface on the 4,500-kva. rotor had been finished along the lines shown in Fig. 9. The respective curves in Fig. 2 show that for 85 deg. cent. rise the new method of ventilation increases the rotor ampere turns 8 per cent. It also increases the volume of generator ventilating air and the rotor windage loss. The effectiveness of the impact method of ventilation increases with the axial rotor length and a preliminary test on the 115,000-kw. machine indicates its radiating capacity to be 15 to 20 per cent higher than the best results previously obtained on shorter rotors.

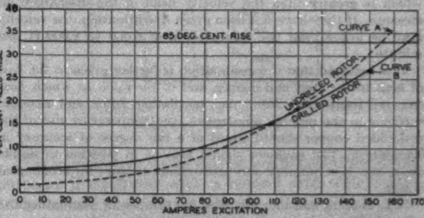

Fig. 2—Rotor Heating on a 4,500-Kva. Turbo-Generator Before and After Its Surface was Drilled

The short-circuit ratio of the 115,000-kw. machine is less than that of the smaller machines previously installed in the Waukegan station. The short-circuit ratio of a machine does not materially alter its efficiency, but if no other restrictions are involved, it does affect its size and cost and should for that reason be kept as low as experience and careful analysis of system characteristics will permit. For generators operated with full field excitation, a short-circuit ratio of 0.5, as has been used in Europe, or even less would probably give ample stability on metropolitan systems. Further for equal stability a double winding generator could have a lower short-circuit ratio than a single winding machine as it is less affected by disturbances.

The heavy weight and large diameter of the forging required for the rotor of the 115,000-kw. machine taxed the art of steel making to the limit. The loss of such a forging due to a blemish would be a serious matter and increase the cost of the machine. Until further progress is made in steel making it seems economically necessary for still larger rotors, to develop a construction reducing weights and diameters of the forgings for the component rotor parts.

Carl J. Fechheimer: When considering the construction of a machine of the large output and high speed described in this paper, it is well to regard the limitations imposed. It is well known that the limits are in the rotor, and they are imposed by mechanical stresses, critical speed, and temperature rise. The use of the better grades of steel, annealed or heat treated, with greater assurance of homogeneity, has warranted the adoption of higher stresses. Annealing or other heat treatment of the steel insures having material of ample ductility so as to avoid failure, if the elastic limit is exceeded at parts where there is still liable to be stress concentration, and plastic flow then secures more uniform stress distribution. Although the author does not so state, in all probability the running speed is above the first critical speed, and as this practise has been common for two-pole, 60-cycle machines of the larger outputs, there is no reason why the same practise should not be followed for four-pole machines. It is important to consider that the influence of the foundation may be to lower the critical speed, and there is danger of encountering a higher critical speed near the running speed.

The scheme adopted for rotor ventilation is ingenious. Determination of the air volumes that flow through the ventilating holes by means of models is in accordance with the desirable methods in use when such a complicated phenomenon as air flow is to be studied. Model tests are, however, not always easy to make in such a way that the conditions in the machine are completely simulated, and measurements are ofttimes difficult and may lead to false conclusions. As the author has not described the model and methods of measurement, it is difficult to comment at length. In this case it is well to consider, in addition to the flow in the rotor ducts as such, the effect of the variable back pressure in the air gap, and the loss of head at emerging, which is greater than the velocity head of the discharged air streams. If they have not been given due attention, the velocity may be lower than the values given of 6,000 to 8,000 ft. per minute.

It is believed that if consideration is further given to the flow of heat in the steel and copper, and to the rates at which heat can be transferred from the ventilating holes and external surfaces to the moving air streams, the temperature rise of the embedded copper should admit of a fair degree of accuracy in calculation. The engineer should also be in position to decide upon the best number and proportions of holes for economical design.

It is well to consider also the importance of ventilating the end windings of the rotor adequately. Cases have arisen in which the length of the outer coils is sufficiently great to cause large temperature differences when the ends were not ventilated. It is of interest to note that lower temperatures can be secured by reducing the sections, thereby raising the air velocities, even though the air volumes are reduced somewhat thereby.

As the rotor temperature rise depends upon the losses, it is interesting to note that the short-circuit ratio has been reduced about 0.67. This is in accordance with present tendencies in design. It is doubtful, however, whether a further reduction is warranted, as there would be but little reduction in excitation, and other effects, such as stability, must be given adequate consideration.

Philip Sporn: Was the use of hydrogen given any consideration in connection with the design of the machine in question? It seems to me that in a machine of this size there was a considerable margin to work on in order to make hydrogen justifiable. Besides the undoubted improved performance of an 18,000-volt winding due to the use of hydrogen, it would seem as if there was a possibility in this case of raising the efficiency to possibly as high as 99 per cent. If this was the case, it would have increased the rating of the machine by well over 1,000 kw., and an additional 1,000 kw. would obviously justify considerable extra expenditure. If hydrogen was considered, it would be interesting to obtain the estimated increase in cost and also the estimated increase in efficiency.

R. B. Williamson: Mr. Mortensen's discussion brings out some of the experiments and investigations upon which the design of the 115,000-kw. generator was based, and serves, for that reason, as an amplification of the paper. His remarks pertaining to the short-circuit ratio of turbo-generators are of interest and warrant consideration.

In answering Mr. Sporn's question with regard to hydrogen cooling, it can be said that the advantages of this type of ventilation were not considered of sufficient importance to warrant its use in this installation.

Mr. Fechheimer is correct in his assumption that the rotor design of the 115,000-kw. generator is such that its first critical speed is below its operating speed. This practise has been followed for the last 20 years by the Allis-Chalmers Manufacturing Company, not only on the 3,600-r.p.m., but also on the 1,800- and 1,500-r.p.m. generators and has given good results. In no case have operating difficulties been experienced on that account. With further increases in rotor length and weight, the danger that the second critical speed of the combined rotor, rotor bearings, and generator foundation may coincide with the running speed of the rotor, makes a most careful study necessary of the design and proportioning not only of the generator rotor but also of its bearings and foundation.

We agree with Mr. Fechheimer that it is difficult to make a model test for rotor ventilation which anywhere nearly represents actual conditions. Although the model mentioned in the paper was no exception to this, nevertheless the air velocities and general results obtained seemed sufficiently encouraging to warrant the application of the rotor ventilating system, described in the paper, to the rotor of the 4,500-kva. machine mentioned in Mr. Mortensen's discussion. The test data obtained on the 4,500-kva. machine were used as a basis for the calculations of the rotor heating on the 115,000-kw. machine. Subsequent tests bear out that the advantages of this method of rotor ventilation increase with the axial rotor length. The results thus far obtained, indicate that this type of ventilation is adequate to cool rotors of considerably greater axial length than the rotor for the 115,000-kw. machine.

The Mercury Arc Rectifier Applied to A-C. Railway Electrification

BY OTHMAR K. MARTI*

Member, A.I.E.E.

***Synopsis.**—A new commutatorless motor with series characteristics has been developed and is briefly reviewed. The motor is particularly suitable for traction purposes and can be supplied from an overhead trolley at the usual a-c. electrification voltages and any commercial frequency.*

It is shown how it is possible, by the use of a grid-controlled rectifier, to eliminate not merely the commutator of the motor, but practically all of the expensive control, switching, and reversing equipment commonly used on a-c. and d-c. locomotives. Regenerative braking is also made inexpensive and practicable.

The first part of the paper explains the general theory of the grid-controlled rectifier which is necessary for an understanding of the commutatorless motor.

The data and layout of a 1,000-hp., 50-cycle, 15,000-volt, single-phase locomotive, now under construction, are given.

* * * * *

INTRODUCTION

THE extensive research work carried on for improving the mercury arc rectifier has led not only to improvements in its operation but also to entirely new applications of the device, and to new applications of the valve action on which its rectifying property is based.

In recent years considerable experimental and development work has been carried on with rectifiers provided with control grids, utilizing the grids for interrupting short circuits and backfires, for d-c. voltage control, for the conversion of direct current to alternating current, etc. In this paper is described a new application of grid-controlled mercury arc rectifiers in connection with a new single-phase motor for a-c. railway service. By the use of the rectifier it was found possible to eliminate the commutator of the motor and practically all the expensive switching and control equipment commonly used on a-c. locomotives, which will result in considerable simplification of the control, and a reduction in cost.

The experiments carried out on a locomotive equipment with this type of motor have demonstrated the practicability of this scheme. Besides the advantages from the point of view of locomotive operation, this scheme makes it possible to use a power supply of any available frequency, whereas at the present time frequencies of 25 cycles or less are generally required. While it is too early to predict to what this development may lead, the marked advantages of a locomotive equipped with motors of this type, which are already apparent, may revolutionize the practise of railway electrification.

THE PRINCIPLE OF ACTION OF ENERGIZED GRIDS

The phenomena and characteristics of the mercury vapor arc in vacua have been treated in great detail in various scientific journals. Briefly stated, in a tank containing highly rarefied ionized gases only a small potential in a given direction is required to cause current to flow between two electrodes of certain types, while a much larger potential must be applied to the electrodes in the opposite direction before an appreciable current flows.

Fig. 1 shows an evacuated vessel with two electrodes: an electron-emitting electrode, *c*, called the cathode, and an electrode which does not emit electrons, *a*, called the anode. The cathode can be made to emit electrons by raising its temperature, by imposing a sufficiently high voltage between the anode and the cathode, or by striking an arc by contact. By using a highly evacuated tank, and by using mercury for the cathode material, a mercury arc power valve is obtained, of a high current-carrying capacity.

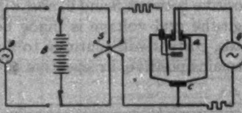

FIG. 1—ELEMENTARY DIAGRAM OF A GRID-CONTROLLED MERCURY ARC VALVE

This mercury arc valve can be made useful for many purposes if equipped with a control grid which is introduced into the path of the arc. This grid is insulated from the anode *a*, and may be energized from an outside source of potential, such as a battery, auxiliary transformer, generator, or a combination of these sources. Non-energized grids or screens are also used to a large extent in mercury arc rectifiers for a number of purposes.*

In all considerations stated below it will be assumed that the cathode is brought into a condition such that it emits electrons. If the battery *B* is so connected to the grid as to make it positive with respect to the cathode, then current from the generator *G* will flow from the

*Engr.-in-Charge, Rectifiers and Rly. Equipment, Allis-Chalmers Mfg. Co., Milwaukee, Wis.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

*See Marti and Winograd, "Mercury Arc Power Rectifiers," (McGraw-Hill), pp. 42, 227, 232, 397.

anode *a* to the cathode *c*. Reversing the polarity of this applied potential, so that the grid is negative with respect to the cathode, will prevent any current from flowing from the anode to the cathode, provided the current is not already flowing when the negative grid potential is applied.

If the sequence of the changing of the grid potential is according to curve 1-2-3-4-5-6-7-8 in the lower part of Fig. 2, and the voltage e_g of the generator *G* of Fig. 1 is as shown in the upper part of Fig. 2, then the operation of the valve is as follows:

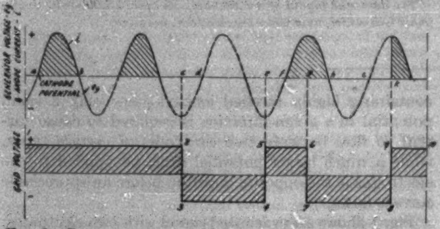

FIG. 2—CONTROL OF ARC BY MEANS OF POSITIVE AND NEGATIVE GRID POTENTIALS

Current will pass during the interval 1 to 2 every time the impressed generator voltage is positive. Since the grid is negatively charged from 3 to 5, no current will flow when the generator voltage becomes positive at *d*. However, current will start to flow at *f*, as the grid voltage is positive between 5 and 6, and will continue to flow although the grid voltage is made negative at *g*; in other words, current will continue to flow as long as the anode remains positive, irrespective of the potential of the grid. Due to the fact that the grid voltage is negative from 7 to 8, current can start to flow only at *k*, and will continue as long as the anode is positive; the anode therefore passes current only during one-half of the positive alternation.

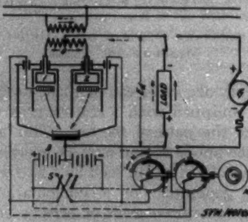

FIG. 3—CONTROLLED-GRID VALVE THAT CAN BE USED EITHER AS A RECTIFIER OR A D-C. TO A-C. CONVERTER

Applying the above considerations to a simplified two-anode rectifier, as shown in Fig. 3, the working of energized grids can readily be followed, and the many possibilities of such a controlled rectifier become evident. Let the primary side of the transformer be impressed with a sinusoidal a-c. voltage and let the grids be non-energized. Then the anodes will be positive during alternate half-cycles. During the half-cycle that anode 1 is positive, current will flow from anode to cathode through the load circuit, as indicated by the solid arrows. When anode 2 is positive, current will flow from anode to cathode through the load circuit, as shown by the dotted arrows. The current therefore flows through the load circuit in the same direction during both halves of the cycle. The same rectifying action will take place if a positive potential is applied to the grids during the intervals when the voltages of the corresponding anodes are positive. This could be accomplished by throwing the switch *S* (Fig. 3) from one position to the other after each half-cycle, making the grid of anode 1 positive during the half-cycle when anode 1 is positive, etc., or by rotating the commutator *C* at synchronous speed by means of the motor *M*.

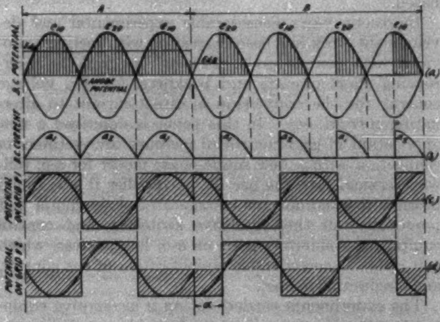

FIG. 4—VOLTAGE REGULATION AND CONTROL BY MEANS OF ENERGIZED GRIDS

This is illustrated in Fig. 4. Section *A* shows the anode voltages e_{10}, e_{20}. The shaded portions represent the d-c. voltage wave (neglecting the arc drop). Section *B* represents the d-c. wave for a resistance load. Sections marked *c* and *d* indicate the potentials applied to the grids; the shaded blocks represent the potentials if direct current is used, with a reversing or rotating switch, as shown in Fig. 3, and the sine waves represent the potentials if alternating current is used.

In *A* of Fig. 4 is shown the condition when the grids are made positive at the instant when the corresponding anodes become positive. Each anode then operates during half a cycle, and the average d-c. voltage is shown by line E_{d_A}. In *B* of Fig. 4 is shown the condition obtained by shifting the brushes of the rotating switch *C*, Fig. 3, through the angle α. The grid potential then becomes positive α electrical degrees after the anode potential, and the point at which the anodes start firing is delayed by the angle α, which reduces the d-c. voltage to the average value E_{dB}.

It can therefore readily be seen that by shifting the brushes of the commutator *C*, that is, by changing the timing with respect to the voltage of the anodes, the rectifier can be stopped from passing current, without interrupting the primary supply (see Fig. 2, interval 3 to 4), or the voltage can be changed from the maximum value E_{dA}, to a value E_{dB}, or as low as zero. The source of potential for energizing the grids, the battery *B*, can be replaced by an a-c. source, which could be an auxiliary transformer, a small generator, or the like.

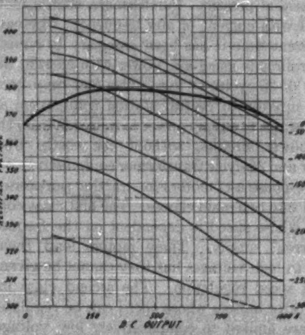

Fig. 5—Grid-Controlled Six-Phase Rectifier (without Inter-Phase Transformer)

Six-phase voltage superimposed on a d-c. grid potential, lagging anode voltage by 60 deg.

For controlling the grids of power rectifiers only a fraction of an ampere per anode is required. It therefore follows that the arrangement for controlling large units makes use of very simple and inexpensive equipment, doing away with much costly control, regulation, and protective apparatus. These advantages will become particularly evident in the description of the new motor and locomotive.

Voltage Regulation and Compounding of Commercial Rectifiers

Fig. 5 shows some experimental curves obtained by imposing a voltage on the grids of a six-phase rectifier. The diagram of connections is shown in Fig. 6. The grid voltage consisted of a negative d-c. voltage, on which was superimposed a six-phase a-c. voltage lagging the respective anode voltages by 60 degrees. The rectifier transformer was connected in six-phase star, without an interphase transformer. The light lines represent the regulation curves of the rectifier with the d-c. component of the grid potential varying from zero to 300 volts. The steep regulation curves are characteristic of this type of rectifier transformer connection.

The heavy line has been constructed from calculations based on the experimental regulation curves, and shows the regulation curve that would be obtained if the d-c. component of the grid potential were decreased uniformly as the load on the rectifier increased. As can be seen from this curve, such a control of the grid potential would give a flat-compounded rectifier, with a regulation curve very similar to the type obtained by flat-compounded generators. The high peak on this curve is of course due to the high regulation obtained with this particular transformer connection.

It is quite obvious that other combinations of d-c. and a-c. potentials can be applied to the grids, so as to obtain automatically almost any form of regulation desired. The broken horizontal line shows a regulation curve that could be obtained by the proper control of the grid potential. Such a curve could be obtained by varying the d-c. potential, the a-c. potential, or the phase angle of the a-c. potential on the grids with respect to the anode voltage. The d-c. voltage of the rectifier can be controlled as a function of the d-c. load, or could even be maintained constant, irrespective of any fluctuations of the a-c. voltage.

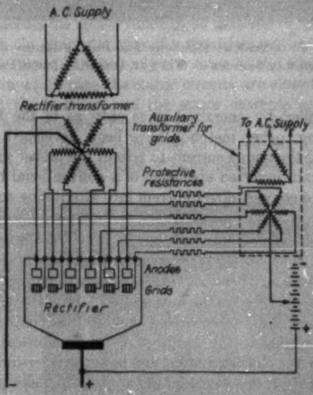

Fig. 6—Connections Used in Obtaining Curves Shown in Fig. 5

Fig. 7 shows a 3,000-kw. mercury arc rectifier of standard design with bushings and connections for grid control, at the West Allis Works of the Allis-Chalmers Manufacturing Co.

Inverted Rectifier

In the arrangement shown in Fig. 3, let us replace the load by a d-c. generator. If a positive voltage is applied to the grid of anode 1, current will flow through the left-hand portion of the secondary winding of the transformer, inducing a voltage in the primary winding.

After a certain time interval let the grid of anode 2 become positive, and current will start to flow through the right-hand portion of the secondary winding of the transformer. Let us assume that at the same time the current in anode 1 can be reduced to zero by some means or other, then the rectifier and associated equipment would be nothing else than a converter feeding power from the d-c. into the a-c. network. Although the flow of current from generator G through the anodes can be controlled by energized grids only as to the time of starting, other methods have been developed for reducing the anode current to zero in the proper sequence to obtain inverted operation of a conventional rectifier so as to convert direct current into alternating current.*

Fig. 7—3,000-Kw. Mercury Arc Power Rectifier for Railway Service on Test at Allis-Chalmers Plant

This feature opens up great possibilities for the now fully developed mercury arc rectifier, and many new applications for the mercury arc valve. One of the most important of these applications to become practicable will be described in the next section. It will be seen how the controlled valve action and voltage control have been applied to the design of a commutatorless motor with series characteristics, and how the inversion of the rectification process has been applied to make possible regenerative braking of a locomotive equipped with such motors.

Commutatorless Single-Phase Railway Motor for any Characteristic and any Frequency

For some time portable substations equipped with mercury arc rectifiers have been built abroad and in this country. As far back as 1914 a 250-hp. motor car, equipped with a mercury arc rectifier, was in service in this country, on the New York, New Haven and Hartford R. R. As some experience is therefore already at hand, it will not be a novelty to put a rectifier on a locomotive and use it as a mobile electric power converter.

During the last few years the mercury arc rectifier has influenced the electrification of railroads to a very great extent, because of its ability to convert a-c. to d-c. power at high voltages and with a high degree of economy and reliability. Again, it is the rectifier which may give another impetus to railroad electrification, for, as indicated in the subtitle to this section, it is now possible, by the use of a commercial mercury arc rectifier equipped with the grid control described above, to build a commutatorless motor which does not require the elaborate and costly switching, reversing, and control equipment used at present. Furthermore, such a motor can be used with current of any frequency, whereas up to the present time it has been necessary to supply electrified railroads using a-c. power with current at a frequency of 25 cycles or less. This fact may be of particular interest to central station companies, as they would be able to supply power to railroads from their 60-cycle power circuits, without the costly frequency changer and 25-cycle transformer equipment.

Single-phase a-c. motors for traction purposes can be divided into two main classes. The first class comprises motors whose speed is dependent on the frequency of the current supply. These motors lend themselves readily to high voltages but they cannot be given a continuous speed regulation. The second class includes commutator motors whose speed can be regulated, but which are limited to comparatively low voltages and frequencies, due to the presence of the commutator. The commutator also makes the construction of the motor and its control very expensive, and involves the troublesome difficulties inherent in commutation.

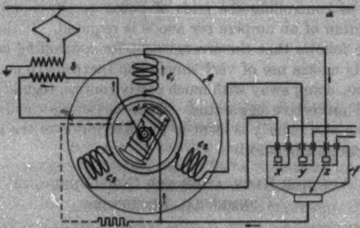

Fig. 8—Elementary Commutatorless Motor

In a motor of the second class, it is possible to replace the commutator by a series of electric valves, *viz.*, a mercury arc rectifier, by the use of which the above-mentioned disadvantages are obviated. As will be seen below, this scheme can be applied to single-phase motors so that relatively high voltages can be used, thus reducing the size and weight of the copper used in the connections. At the same time, a very desirable speed-tractive effort characteristic can be obtained. Further-

*See Kern, *Bulletin Schweizerischer Elektrotechnischer Verein*, 1931, p. 538.

more, all expensive control, switching, and reversing equipment is dispensed with, while only a very simple and cheap grid control is added. As explained above, only a very small current is needed for the grid control, and the cost of the equipment is naturally low.

In Fig. 8, *a* designates a single-phase a-c. supply line, and *b* a single-phase transformer. The transformer is connected to the stator winding *c* and rotor *d* of the motor *e*, both of which are connected in series, using two slip rings. The rectifier *f* should be located as near as practicable to the motor. It is equipped with grids and control, as shown in Fig. 3. The motor is shown as a salient pole machine, but does not have to be such. In the following description it will be assumed that the field of the motor is rotating, and that the armature is stationary. It is evident, however, that this could be reversed. Each armature winding is connected to one anode of the rectifier, each anode being provided with control grids for regulating the flow of current.

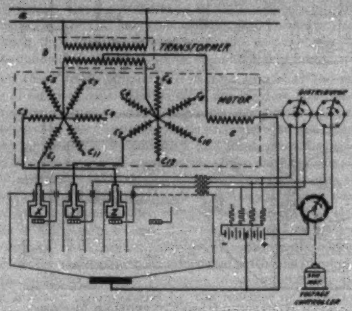

FIG. 9—COMMUTATORLESS MOTOR UTILIZING BOTH HALVES OF VOLTAGE WAVE

In operation, let it be assumed, first, that the rectifier equipment is in the position shown, and that one grid (of anode *z*) is positively energized through the distributor. This grid accordingly permits current to flow through the anode which it controls. All other grids will be negatively energized thus preventing current from flowing through their anodes. As the primary winding of transformer *b* is energized from the line, a half-wave current will flow through the winding of the rotor *d* and through c_1, as indicated by the arrows. As can readily be seen, the field produced in the windings c_1 and *d* will produce a torque which causes the field *d* to rotate and reach, with respect to winding c_2, the position which it previously had with respect to winding c_1. At the same time, the shaft of the motor *e* brings the brushes of the distributor to such a position that the grids of anodes *z* and *x* are now negatively energized, while the grid of anode *y* is positively energized, permitting current to flow from the anode *y* into the winding *d*, and through c_2. The above process is repeated in sequence for all windings of the stator, thereby producing a continuously rotating motion of the rotor.

It can be seen from the above that the motor simply constitutes a load for a conventional rectifier *f*, which may therefore be provided with all improvements known to the rectifier art. In particular, the voltage impressed on the stator windings may be regulated by any of the various means of voltage regulation used with rectifiers, and which have been described above. This voltage regulation can be used here, the voltage being reduced to a low value when the motor is started, and later on being adjusted for purposes of speed regulation. There are also other means for changing the speed or the characteristics of the motor, by a control of the anode grids.

As stated above, this arrangement utilizes one-half of the applied voltage wave. The arrangement shown in Fig. 9 will permit the utilization of both halves. The regulation of this motor is also effected by means of energized grids, and the speed can be varied and the characteristics altered by the same means.

The two motors mentioned above both have series characteristics which are desirable for traction purposes. In the first motor, a resistance could be connected across the stator winding, so that the motor can be given the characteristics of a repulsion motor. It is also possible to connect only the rotor to the source of power, in which case the stator circuits are closed only through the rectifier, and the stator currents are obtained by induction through the rotor. The stator, being then no longer connected to the circuit, can be wound for whatever voltage is found most desirable.*

FIG. 10—COMMUTATORLESS RECTIFIER MOTOR ON TEST

The operation of the transformer, rectifier, and motor, does not require a source of any definite frequency. This makes it possible to operate the unit with power from either 25-cycle or 60-cycle commercial lighting and power circuits. Moreover, if properly designed, a single motor can be operated on lines of different frequencies. It may even be possible to omit the transformer, and feed the motor directly from the line, through the recti-

fier. This would result in an arrangement particularly desirable for suburban lines using multiple-unit cars. Only one rectifier is required to control all the motors of one locomotive or motor car. We therefore have a very simple arrangement with the greatest possible range of control, namely, from zero to maximum, using a very light and inexpensive grid-control equipment, and without the least degree of energy loss.

With a suitable arrangement of apparatus, this type of motor can also be used for regenerative braking while the locomotive or car is proceeding down grade.

Fig. 10 shows the first experimental model of such a commutatorless motor directly coupled to a generator as load, and with a commercial rectifier of very large capacity. The control hand-wheel is visible on the right.

In this connection it is of interest to note that Brown, Boveri & Co., Ltd., of Baden, Switzerland, is at present building a single-phase locomotive to be operated directly with single-phase power of 50 cycles at 15,000 volts. The locomotive is of standard gage, and is equipped with two motors of 500 hp. one-hour rating, for a maximum speed of 90 km. per hr. (56 mi. p. hr.). (See Fig. 11.) It is designed for regenerative braking. This locomotive has no commutators, tap switches, starting resistances, nor reversing switches, in the motor circuit. All such equipment is replaced by a high-voltage mercury arc rectifier with control grids. The tests with this locomotive will be highly significant in view of the possible utilization of alternating currents of commercial frequencies for the electrification of main-line railroads.

Discussion

L. R. Ludwig: For a great many years engineers have appreciated the advantages which may be gained by introducing grids into mercury arc rectifiers for the purpose of controlling them. A large number of patents has demonstrated the realization of the possibilities inherent in this type of device; in particular, the early fundamental patent on inverters (L. W. Chubb, Re. No. 17693) and later patents by Slepian have helped lead the way in these developments. Today the average design engineer accepts the possibility of a grid-controlled rectifier, perhaps without enough reservation as to the difficulties which the grid carries with it. Inherently, a grid-controlled rectifier is similar to a uni-directional switch, provided suitable extinguishing means are supplied if a d-c. circuit is to be interrupted. However, the grid-controlled rectifier suffers from the very serious disadvantage that the grids frequently lose control without apparent cause. In this respect the grid-controlled rectifier is much inferior to a switch because, as pointed out in a paper by Slepian and Ludwig,* the loss of grid control, which is most often in the nature of a backfire, does not occur above certain definite limits but may occur at random throughout any operating range of current or voltage. In other words, the loss of control of the grids constitutes a major problem, the solution of which today is more incomplete than that of the backfire problem in general. Another serious cause of loss of control of the grids when such devices are used as inverters is the fact that a relatively long deionizing time is necessary for a current zero in order for the grid to gain control. Careful measurements of this time made by Slepian and Crago in 1923 indicate hundreds of microseconds. In the inverter circuit the necessity for this deionizing time requires the use of special commutating means such as condensers, which must be comparatively large.

From these brief comments, it can be seen that the requirements of an ideal controlled rectifier are freedom from backfires and freedom from a long time lag necessary before the grid can gain control of the discharge to its respective anode. The large amount of research work which has been done by electrical manufacturers toward the perfection of the mercury arc rectifier and its grid-controlled brother will probably soon make the use of such devices technically possible. However, if one considers what is really required of the rectifier or inverter in an electrical circuit, it will readily be seen that the large and rather cumbersome devices which are on the market today really represent a rather crude development as compared with the device which may be imagined as being sufficient to accomplish the purpose which is really accomplished by the rectifier or inverter. The present size and complexity of this type of apparatus are no doubt due to the as yet imperfect understanding of the nature of backfire. For example, the ideal rectifier may be quite small, having very low loss and free from the complexity of the various grids and shields as employed at present. The ideal converter might well be imagined as a similar device in which satisfactory control is obtained perhaps with means other than grids. Consequently, there may be some question as to whether the present rectifier and converter must not be very materially improved before startling changes in the transmission of electrical power can be expected from their use.

It has also been recognized for some time that rectifiers may be used instead of commutators in conjunction with rotating electrical machinery. However, it would be no more correct to state that the rectifier can be used to replace the commutator than it would be to state that a gasoline engine can be used to replace the horse. Both gasoline engine and horse may be used as a source of power for locomotion, but certainly no one would expect to hitch a gasoline engine to the shaft of a wagon for the purpose of pulling it. Similarly, the rectifier is not the exact counterpart of the commutator. Two differences exist: (1) the rectifier is a uni-directional switch, whereas the commutator and brush will pass current in either direction, and, (2) the rectifier for practical reasons must have a comparatively small number of anodes or segments, whereas the commutator usually has a large number. The result is that when a rectifier is used in place of a commutator, as suggested by Mr. Marti, the utilization of the windings on the motor is not nearly so good as the utilization if a commutator is used. For this reason, one may question whether it would not be better practise to use a controlled rectifier merely as a frequency-changer without direct regard to the motor, and to use with it some type of motor in which the utilization of copper is considerably better. Certainly with this poor utilization, the requirements of the controlled rectifier as to size, cost, and reliability seem to be much greater than can be met at the present time.

R. E. Hellmund: The possibility of using rectifiers on locomotives running on an a-c. system has been rather intriguing to engineers ever since the conception of the mercury arc rectifier. This is evidenced by the early operation of a rectifier car by the Westinghouse Company on the New York, New Haven and Hartford system in 1914. The possibility of commutatorless motors operated by means of rectifiers was conceived very soon after the advent of the rectifier, as is evidenced by the early work of Chubb, Slepian, Hazeltine, Alexanderson, and others. The failure to introduce such arrangements for commercial operation was primarily due to the fact that they could not economically compete with arrangements using the ordinary single-phase commutator motor, and in the case of the schemes of operating commutatorless motors the development of suitable rectifiers in the early days was perhaps not far enough advanced to give sufficiently reliable operation. In the meantime, considerable progress has of course been made in the development of rectifiers and similar electronic devices, but probably even greater advances have been made in the design of single-phase motors by those engineers who realized the possibility of this type of motor for railway work. As a result of such progress in both lines of activity, their relative position today is about the same as in the early days, namely, the present rectifier arrangements cannot compete economically with single-phase commutator motors.

The fact that the single-phase commutator motor presents certain engineering problems in connection with commutation and that as a matter of course such problems have been discussed a great deal by the interested engineers, has led to the impression that if only a commutatorless motor could be devised for an a-c. railway the millennium would have been reached. In other words, the fact that the single-phase motor offers one major problem in its design has distracted attention from the fact that it offers some very marked advantages over any other type of motor for conditions prevailing in railway work. The very feature which has been introduced in the single-phase motor design to take care of the commutation problem, namely, the use of a large number of poles, brings with it the possibility of obtaining a higher rating within the definitely limited space available and at a lower weight than is possible with other motors.

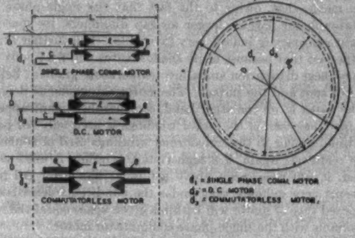

Fig. 1

This can best be pointed out by reference to Fig. 1. With an available outside diameter D and a large number of poles, the core naturally will be shallow, giving an air-gap diameter d_1 in the case of a single-phase motor. In a d-c. motor on a locomotive, at least an appreciable part of the total line voltage has to be applied to each motor, which necessitates large distances between brush-holders and, as a consequence, a small number of poles. This in turn requires appreciable space for the yoke section and the field coils, so that the air-gap diameter d_2 will have to be very much smaller. In most commutatorless motors the number of poles must also be made smaller because such motors, unlike the single-phase commutator motor, are unable to operate above synchronous speed. In the case of induction and synchronous motors this is of course evident, but it is also true with the motor described in the paper unless additional complicated

---

Backfires in Mercury Arc Rectifiers, A.I.E.E. Trans., March 1932, p. 92.

means are introduced. While with the arrangement given, a number of cycles can be used in succession for each of the windings, thus making it possible to operate at low speeds; there seems at present to be no simple and inexpensive way of stopping the current flow in any one winding before the end of the half cycle. This means that with a given number of poles the speed cannot be increased indefinitely, which in turn means that in order to obtain high speeds a small number of poles has to be chosen. As a consequence, the depth of the stator core will be greater than with the commutator motor and therefore the air-gap diameter d_3 will be smaller. The same figure gives a comparison of the three types of motors with regard to filling the limited width available in railway work. The latter is usually taken up by some clearances, by the core width, the length of the coil-end connections, and the commutator where there is any. In the upper figure showing the single-phase motor, the commutator is long, but on account of the large number of poles the coil ends are short. In the second figure illustrating a d-c. motor, the commutator is shorter but the end connections are longer. In the third figure, representing the commutatorless motor, there is of course no commutator but the coil ends are long. If slip-rings are used inside of the bearings, as usually will be the case, further space may be taken by the slip-rings and the brush-holders, unless it is possible to locate them under the winding. In other words, the length of core available for the three types of motors probably does not vary to any great extent. This then means that, owing to the fact that the single-phase commutator motor permits larger air-gap diameters, its space and weight efficiency is indeed very favorable. It is further favored by the fact that because of its shallow cores and field coils there is good heat dissipation and a low temperature gradient between the hot spot and the surface. The motor arrangement described in the paper is, on the other hand, considerably handicapped by the fact that each of the stator windings is used only for part of the time, similar to the transformer windings used in connection with rectifiers. Again, if a high-voltage winding is used as proposed, it will necessarily prove a further handicap. All in all, it seems very unlikely that under the conditions described the proposed type of motor will within a given space equal the rating obtainable with the single-phase commutator motor.

With this picture of the motors before us, it is not difficult to see that, with no gain in the motor situation, the addition of a rectifier to the locomotive in the present state of the art is not likely to lead to an all-round economic solution from either the first-cost or the maintenance point of view. It is true that commutators as well as switches require some maintenance, but this is also true to a greater extent with the rectifier. Further consideration must be given to the fact that rectifier arrangements will be handicapped by the necessity for filtering equipments on the locomotive if telephone disturbances are to be avoided.

It is suggested in the paper that the proposed scheme might be used for 60-cycle electrification, thereby obviating the necessity for 25-cycle systems. Here again it so happens that although the considerations of the motor commutating problem have brought about the use of 25 cycles for railway work, such a system is advantageous from various points of view. The early claims that the 60-cycle system would eliminate rotating conversion apparatus have not materialized because it has been found that phase-converting apparatus would be necessary anyway. Furthermore, the use of 25 cycles under railway conditions, with the heavy loads of changing location, has shown quite some superiority from a voltage regulation point of view and also as far as telephone interference is concerned.

This discussion of the economic conditions is not intended to convey the idea that studies like that presented in Mr. Marti's paper are futile. However, the scheme presented, like many others previously suggested for the utilization of electronic devices both for traction and other purposes, will be dependent to a great degree upon further developments of electronic devices. Many of them will not find commercial utilization until the electronic devices have been developed to the point where they are considerably less expensive and where a greater reliability of various grid control schemes has been obtained.

E. F. W. Alexanderson: The vacuum tube technique has many ramifications and promises to become an important factor in most branches where electric power is used. One of those possibilities is to substitute grid control rectifiers or thyratrons, as we call them, for the copper and carbon brush commutator in the operation of adjustable speed motors. The largest field for the use of adjustable speed a-c. motors is undoubtedly railroad electrification and much thought and research have been given to this subject in the last ten years or more by those interested in the vacuum tube technique. Those who look at this development from outside may well ask: Why, if the problem has been clearly understood for so long, is the practical solution so slow to be realized? The answer to this is apparently that the vacuum tube technique is not a simple engineering problem but an evolution and like all evolutions it is necessarily slow. It involves the work of the physicists who are contributing new knowledge of electricity and matter. It involves the manufacture of the vacuum tubes themselves, and the evolution of a new technique for embodying those new principles in practical devices and finally, it involves the electrical engineers who must interpret the usefulness of these devices with relation to the more conventional types of electrical machinery.

The history of this evolution for the last ten years is that new principles have constantly been introduced in the manufacture of superior vacuum tube devices and these devices in their turn have made possible new and improved methods of engineering application. The commutatorless a-c. motor developed by the Brown-Boveri Company and described by Mr. Marti is one of the steps in this evolution. From personal experience I can say that motors of this type will operate with satisfactory characteristics and I do not doubt for a moment that a motor just as described can be designed to haul a locomotive.

Another question is: Will such a locomotive be economically competitive with other and existing types of electric locomotives? Serious efforts are being made to answer that question. Personally I am of the opinion that this development will lead to such a practical solution and my reason for this belief is that progress of the vacuum tube technique is rapidly leading to new and superior forms which in their turn make possible improved methods of correlating the power system, the vacuum tube, and the motor. From the point of view of engineering research, this subject is of intense interest. But no matter how great our enthusiasm, I think it is better and wiser to admit that from the point of view of practical railroad electrification it is not possible to discuss this matter intelligently until we have before us a locomotive with vacuum tube commutation which is not only operative but is economically competitive with the now existing types. If, and when, these hopes are realized it will mean a substantial boost to the spread of railroad electrification because locomotives of the new type may be operated side by side with locomotives of the old type on the same lines, each type filling its place according to its own merits. From this point of view, it is fortunate that in this country a power frequency of 25 cycles rather than the lower frequency of $16^{2}/_{3}$ cycles has been adopted for railroad electrification because 25 cycles is better adapted to various uses. The anticipation of new and improved types of locomotives is thus no reason for delaying practical progress in electrification, because the new methods when realized, will fit in with the old plans.

R. G. McCurdy: The developments described by Mr. Marti on rectifiers provided with control grids open up some very interesting possibilities in the way of new problems for the telephone companies as well as possible advantages to power and electric railway companies.

We have had, of course, no experience with the new applications described by Mr. Marti but must base our comments on our experiences with these devices as used for conversion from alternating to direct current.

Considerable information has been published in the technical press, including the TRANSACTIONS of the Institute, regarding the effect of mercury arc rectifiers on the wave shape of systems to which they are connected and the resulting effects on coordination with telephone lines. This has been more particularly in reference to the effects on the d-c. side. The joint studies which have been made of the problem by the electrical manufacturing and telephone companies have led to the development of filters for the d-c. side which reduce the harmonic voltages and currents to values which permit satisfactory coordination between the d-c. systems and nearby telephone systems. These have been employed in situations where it appeared that conditions of proximity with the telephone plant were such as to justify their use.

The a-c. side of the device presents a more difficult problem. As compared to the d-c. side the percentage harmonic voltages and currents are much greater in magnitude. Moreover, there is a larger number of harmonics present. Both of these factors considerably increase the cost and difficulty of filtering. Where the rectifier is close to a source of power of relatively large size and supplied over lines not involved in appreciable exposures to telephone plant, these relatively large harmonic currents are not of importance. The impedance of the system under such conditions is low enough so that no appreciable increase takes place in the harmonic voltages and the telephone interference factor to which they contribute. On the other hand when the rectifier load is a relatively large part of the total power rating of the system, or when lines and transformers of considerable impedance intervene, or if the line supplying the rectifier is involved in telephone exposures, the difficulties in coordination are greatly increased.

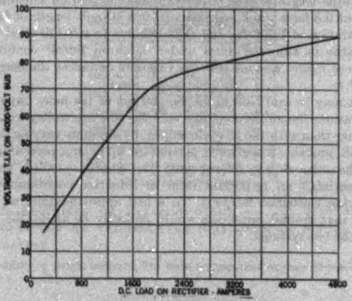

FIG. 2—VARIATION OF VOLTAGE TELEPHONE INTERFERENCE FACTORS ON A 4,000-VOLT BUS

With load on rectifier fed from same transmission system

On balanced polyphase power systems mercury arc rectifiers make no direct contribution to the residual voltages and currents of the system. Thus the usual methods of transposing the lines are applicable. In many cases, however, a distribution system involving numerous single-phase branches involved in exposures with telephone circuits may be supplied from the same system as a mercury arc rectifier. Under these conditions the harmonic voltages introduced by the rectifier will be residual so that means other than power transpositions will need to be resorted to in order to reduce the influence.

In Fig. 2 are shown some values of telephone interference factors on a 4,000-volt bus supplying distribution circuits, as a function of the load on a large mercury arc rectifier supplied from the same high-voltage transmission circuit as this 4,000-volt bus. It will be noted that under maximum load conditions on the rectifier, the bus voltage telephone interference factors are increased by a factor of more than 5:1. It will be apparent that coordination measures which are adequate for the minimum telephone interference factors values may be entirely inadequate when the load on the rectifier is large.

It is well known that the magnitudes of the harmonic voltages and currents on both the a-c. and d-c. sides are dependent in a large measure on the number of phases involved. A 12-phase rectifier for example has materially lower values of certain harmonics than the 6-phase rectifier. The wave shape of the two devices may be made substantially equivalent on the d-c. sides by filtering, a more effective filter however being required with the 6-phase device. On the a-c. side the 12-phase rectifier involves somewhat smaller fifth, seventh, seventeenth, and nineteenth harmonics. The eleventh and thirteenth harmonics are about the same for the 12-phase and 6-phase devices. The telephone interference factors so far observed have been in the ratio of about 1:3 in favor of the 12-phase device.

This matter is being actively studied by the Project Committee on Wave Shape of the Joint Subcommittee on Development and Research of the N.E.L.A. and Bell Telephone System. It is hoped that technical information which will permit the making of quantitative estimates of the effects of rectifiers on the wave shape of supply systems will be soon forthcoming from this committee.

In examining the effect of the controlled grid rectifier as described by Mr. Marti, it seems evident that the load regulation by these means must result in further reaction in wave shape. This may be seen by examining the graphs shown in Fig. 4 of Mr. Marti's paper. The effect on the wave shape of the d-c. side may, of course, be compensated for by suitable modification of the d-c. filter.

While I have not made a detailed quantitative examination of the wave shape of the current of the commutatorless single-phase railway motor described by Mr. Marti, it seems apparent that harmonics will exist in the a-c. side comparable at least with those experienced with the polyphase rectifiers previously mentioned.

Noise frequency induction has not in general been a problem with single-phase railway electrifications due to the small wave-shape distortion experienced, induction at the fundamental frequency being a controlling factor. No doubt the exacting commutation requirements of the single-phase motor have been a controlling factor in this situation. The controlled grid mercury arc rectifier would apparently seem to solve the commutation problems, but at the expense of a considerably increased wave-shape distortion. This may be expected to complicate the problems of coordination between single-phase a-c. railways and telephone circuits. It is hoped that the joint development effort previously referred to in securing inductive coordination with the conventional type of mercury arc rectifiers will lead to methods which may be applicable in the a-c. railway case.

H. M. Trueblood: The possibility of direct utilization of 60-cycle energy on the contact systems of electrified railways has engaged the attention of engineers occasionally in the past, and has led to certain preliminary exploration of its probable reaction on inductive coordination at fundamental frequencies. Mr. Marti's paper brings this question up again in an interesting way. In line with American practise in electric railway and commercial power engineering, the following general observations are based upon a comparison of the use of single-phase 25-cycle and 60-cycle energy upon the contact wire of an electrified railway using the running rails for return. Several factors are involved in a rather complicated way, and simplifying assumptions underlie this preliminary comparison. These are: first, the power supply is unidirectional *i. e.*, it is what is generally known as "stub-end feed;" second, the currents—load or short-circuit—are of the same magnitude in the two systems.

There are involved the following main factors:

Average earth current throughout the inductive exposure (it is chiefly this current, as distinguished from the current remaining in the rails, that causes fundamental frequency induction in communication circuits in the usual case). In addition to differences in track-earth circuit characteristics at the two frequencies, this point involves also the length of feed and the length of exposure.

Relative magnitudes of coefficients of induction at 25 and at 60 cycles. This depends upon the resistivity of the earth and upon the separation between the railroad and the communication line.

The efficacy of shielding conductors at the two frequencies. Such shielding conductors may exist, irrespective of any inductive coordination questions, in proximity to either the communication conductors (for example, cable sheaths) or the railway system (for example, structure ground-wires), or they may be installed primarily for purposes of coordination. Here again the earth resistivity is a factor, and, as exemplified particularly in the case of underground communication cables, the amount of metal in the shielding conductors and its distribution are important.

Estimates have been made of the effects of these factors, using reasonable figures for items of design, and, in the main, experimental data for physical characteristics such as rail impedance, track leakage, etc. It is not proposed here to attempt more than brief summaries. These estimates indicate:

1. That for a representative value of track leakance per track, the ratio of average earth current at 60 cycles to that at 25 cycles does not depart from unity by more than about 10 per cent for lengths of feed ranging from some 3 miles up to 20 miles or more.

2. That the ratio of the mutual impedance of two ground-return circuits at 60 cycles to the same quantity at 25 cycles ranges from 2.2 for 50 ft. separation and earth resistivity of 1,000 meter-ohms to about 1.2 for 1,500 ft. separation and earth resistivity of 10 meter-ohms.

3. That for optimum conditions (zero impedance ground connections at the ends of the exposure) the ratio of the reduction in induced voltage due to cable-sheath shielding at 60 cycles to the corresponding reduction at 25 cycles ranges from about 2.0 for one full-sized cable to about 1.5 for two full-sized cables in adjacent duct runs. (This is for an earth resistivity of 100 meter-ohms.)

4. That the efficacy of track feeders in reducing the amount of current in the earth, for long feeds, is some 5 to 10 per cent (depending on the number of feeders and the number of tracks) better for 60 cycles than it is for 25 cycles.

On the basis of the estimates that have just been summarized and under the above-stated simplifying assumptions, certain statements become possible with regard to the induced longitudinal voltages:

5. The ratio of the longitudinal induced voltage at 60 cycles to the longitudinal induced voltage at 25 cycles is greater when the track leakance, the length of feed, the separation, and the amount of shielding provided are small than when they are large.

6. For an earth resistivity of 100 meter-ohms this ratio ranges from about 2.4 for a track leakance of 0.5 mho per track mile, a 3-mile length of feed, a 50-ft. separation and no shielding, to about 0.8 for a track leakance of 1.0, a 10-mile length of feed, a separation of 1,500 ft., and shielding due to two full-sized cable sheaths in adjacent ducts under optimum (ideal) conditions. (These figures assume that the exposure embraces the length of feed.)

It may be said that in the general run of the more important situations the induced voltage with the 60-cycle trolley would be higher than with the 25-cycle trolley, by amounts varying from a small, probably a negligible, percentage, up to large percentages—of the order of 50 to 100 per cent. This ignores so-called "ground potentials," an important item in inductive coordination involving electrified railways. To a first approximation, we may say that ground potentials would probably be about the same for the two systems.

Insulator Sparkover

Factors Affecting the Sparkover Voltage of Insulators Used on High-Voltage Transmission Systems

BY W. L. LLOYD, Jr.*
Member, A.I.E.E.

Introduction

While the mechanical properties and strength of the various parts entering into the design of a modern transmission system are quite well known, the electrical characteristics of the various parts are often not so definitely understood. This is particularly true of the electrical properties of the insulating parts, including the line and station insulation and bushings used on the station equipment. It is the purpose of this paper to present data upon the sparkover strength of the various parts used for the insulation of modern high-voltage transmission systems.

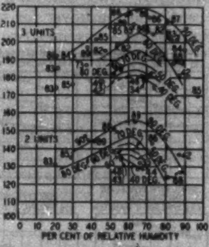

Fig. 1—Effect of Relative Humidity and Dry Bulb Temperature on the 60-Cycle Sparkover of Suspension Insulators

Number on points indicates dry bulb temperature at time of test. Air density = 1.00

Temperature and Barometric Pressure. The effect of temperature and barometric pressure upon the 60-cycle sparkover voltage was determined a number of years ago for sphere-gaps, point-gaps, bushings and various types of suspension and pin type insulators.[1] In this early work it was found that the sparkover voltage of gaps, varies with varying air density factor δ.

$$\delta = \frac{3.92\,b}{273 + t} \text{ in metric units, where}$$

b = barometric pressure in centimeters of mercury
t = temperature in degrees centigrade

At 25 deg. cent. and 76 cm., the air density factor is unity.

Or,

$$\delta = \frac{17.9\,b}{459 + t} \text{ in English units, where}$$

b = barometric pressure in inches of mercury
t = temperature in deg. fahr.

At 77 deg. fahr. and 29.9 inches, the air density factor is unity.

It is generally sufficiently accurate to assume that the change in sparkover voltage is directly proportional to the change in air density. Although the effect varies somewhat with the design of the insulator or bushing, the above rule will usually apply over the practical operating range. For example, the sparkover voltage of three and four unit insulator strings has been found to vary directly with the air density factor down to and including an air density 50 per cent of that occurring at standard temperature and barometric pressure (77 deg. fahr. and 29.9 inches).

Air density affects the lightning sparkover of gaps and insulators in the same general way as for 60 cycles. However, the effect for lightning is usually somewhat less.

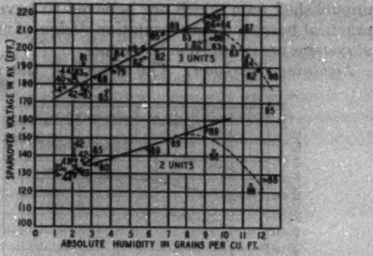

Fig. 2—Effect of Humidity on the 60-Cycle Sparkover of Suspension Insulators

Note that plotting sparkover voltage against absolute rather than relative humidity results in a single curve for all dry bulb temperatures (as indicated by number on points). Air density = 1.00

All sparkover voltages in this report have been corrected to an air density of unity by using the air density factor as given above.

Humidity. Only a small amount of data giving the effect of humidity has heretofore been published.[2,3] Tests made in different laboratories under identical conditions, in so far as A.I.E.E. specifications are concerned, often fail to produce identical results. Data included in this

1. For references see Bibliography.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

paper indicate that the larger part of these differences can usually be attributed to the effect of humidity or water vapor in the atmosphere in which the tests are made. A humidity of 6.5 grains per cu. ft. (65 per cent at 77 deg. fahr.) has been used by this laboratory as the standard condition of humidity in giving out sparkover data. This is equivalent to a vapor pressure of 0.608 in. (15.4 mm.) of mercury.

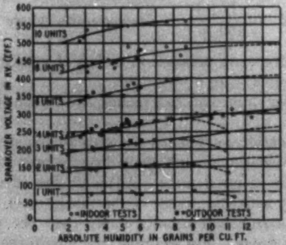

Fig. 3—Effect of Humidity on the 60-Cycle Sparkover of Suspension Insulators

10-in. diameter, 5¾-in. spacing, standard duty. Air density = 1.00

Smoke, Steam, Dew, Fog, Rain, and Surface Dirt and Moisture. While the effects of moisture and dirt have been recognized for a much longer time, specific quantitative data have often been lacking. Some heretofore unpublished data which are believed to have a direct practical bearing on the insulation design of many lines of systems are included in this paper.

Lightning Sparkover. The effects of the preceding factors on the lightning sparkover of various insulations are discussed and some data submitted.

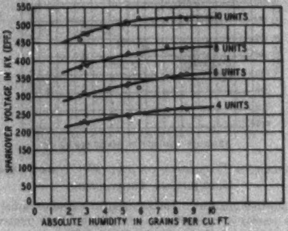

Fig. 4—Effect of Humidity on the 60-Cycle Sparkover of Suspension Insulators

10-in. diameter, 4¾-in. spacing, standard duty. Air density = 1.00

HUMIDITY

Where the humidity for a given sparkover test has been specified it has been common to express the humidity in terms of relative humidity. No confusion would result by such a procedure if all sparkover tests were made at approximately the same temperature. The effect of humidity can then be indicated by plotting sparkover voltage as a function of relative humidity. Sparkover tests are, however, sometimes made over a wide range of temperature and results so plotted are of little value in comparing the humidity effect and in finding an agreement in the sparkover voltage at some given humidity. A single curve of sparkover voltage as a function of relative humidity for different temperatures cannot be drawn. (See Fig. 1.) The effect can only be shown by drawing in a group or family of curves, each individual curve pertaining to a particular temperature. Since humidity has generally been expressed in terms of relative values, it has been difficult to interpret its true effect and different laboratories have found it difficult to agree upon the sparkover voltage at any given humidity. Note that for a relative humidity of 65 per cent, the sparkover for two units varies from 130 kv. to 155 kv., and for three units from 180 kv. to 220 kv. for a temperature variation of 40 deg. to 90 deg. fahr. or plus or minus approximately 10 per cent in voltage even after correction for temperature.

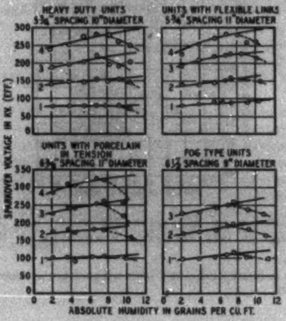

Fig. 5—Effect of Humidity on the Sparkover of Suspension Insulators, 60 Cycles

Air density = 1.00

Fig. 2 shows the same data when plotted in terms of the absolute humidity. The family of curves reduces to a single curve indicating the true effect of humidity. The dip in the curve beyond about 9 grains per cubic ft. will be discussed below.

Fig. 3 presents the sparkover voltage for 10-inch diameter standard-duty suspension insulators having a spacing of 5¾ inches. These tests have been made with four different sets of testing equipment in four laboratories. Three of the laboratories employed artificial humidity control; the fourth was an outdoor laboratory in Pittsfield using natural humidity occurring from day to day and season to season. All these tests were conducted in accordance with A.I.E.E. Standards No. 41. The importance of recording absolute rather than relative humidity is most apparent when the same relative humidity is measured in a spring or fall outdoor test as compared with a summer test. Although the relative humidity may be the same, the absolute humidity because of a considerable change in temperature may be considerably different. Under such conditions, unless the absolute humidity is used, considerable variations are indicated.

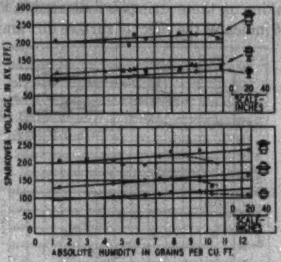

FIG. 6—EFFECT OF HUMIDITY ON THE 60-CYCLE SPARKOVER OF PIN AND PEDESTAL TYPE INSULATORS

Air density = 1.00

The effect of humidity on the sparkover voltage of 10-inch diameter standard-duty suspension insulators having a spacing of 4¾ inches is shown in Fig. 4. The effect of humidity on the sparkover for various types of suspension insulators is shown in Fig. 5 while Fig. 6 presents the effect of humidity on certain sizes of pedestal insulators and a large pin type insulator. Fig. 7 presents similar data for certain sizes of small pin type insulators. The effect of humidity is not great on single suspension disk insulators or on these small pin type insulators.

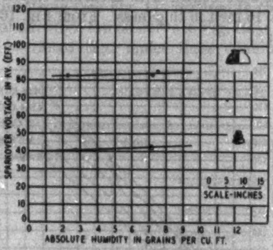

FIG. 7—EFFECT OF HUMIDITY ON THE 60-CYCLE SPARKOVER OF PIN TYPE INSULATORS

Air density = 1.00

Fig. 8 shows the effect of humidity on the sparkover of an oil-filled bushing.

Fig. 9 is a typical humidity curve for the sphere gap. The sphere gap appears to be practically independent of the humidity. Fig. 10 presents the effect of humidity on the 60-cycle sparkover voltage of the needle gap. The data in Figs. 9 and 10 are in agreement with previous data on the effect of humidity on the sparkover of spheres and needles.[3]

Fig. 11 is a plot of the data from Fig. 10 in sparkover voltage as a function of the spacing. The standard needle gap curve is also indicated.

It will be noted that several of the humidity sparkover curves for insulators indicate a lowering of the sparkover for absolute humidities above approximately 9 or 10 grains per cu. ft. That this is an effect of surface moisture or condensation of the water vapor from the atmosphere on the porcelain surfaces at these high absolute (and generally relative) humidities and not an effect in the air gap, is indicated by the absence of this effect in the case of the needle gap and sphere gap, particularly the former. This conclusion is also indicated by the data in Fig. 12 where tests were made on chilled and slightly heated insulators. It is also indicated by the difficulty commonly experienced when tests on insulators at high humidities show a constantly rising sparkover in repeated tests. The surface moisture results in a low sparkover in the initial test. Repeated sparkovers remove this surface moisture and the insulator gradually acquires the higher sparkover resulting from the high humidity. Frequently this increase in sparkover continues for twenty-five or more tests before the sparkover voltage becomes constant at the upper value.

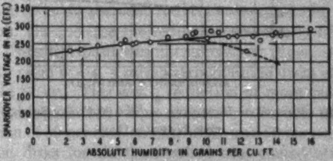

FIG. 8—EFFECT OF HUMIDITY ON THE 60-CYCLE SPARKOVER OF AN OIL-FILLED BUSHING

Air density = 1.00

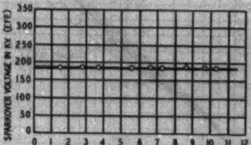

FIG. 9—EFFECT OF HUMIDITY ON THE 60-CYCLE SPARKOVER OF A 25-CM. SPHERE GAP SPACED FOR 187 KV.

Air density = 1.00

Smoke, Steam, Dew, Fog, Rain, and Surface Dirt and Moisture

The 60-cycle sparkover of clean 10-inch diameter standard-duty suspension insulators of 5¾-inch spacing for dry, light rain, and heavy rain conditions is shown in Fig. 13. The tests apply to insulators in a vertical position. Rain tests with the insulators in a horizontal position indicate no lowering of the sparkover by rain with the rain directed either at right angles to the string or from, or towards, the line end at an angle of 45 deg. to the string and always at 45 deg. from the vertical. On a horizontal string rain sufficiently improves the poor voltage distribution along the string so as to raise the rain sparkover to that of the dry. The drip along the vertical string overbalances this effect and actually lowers the sparkover.

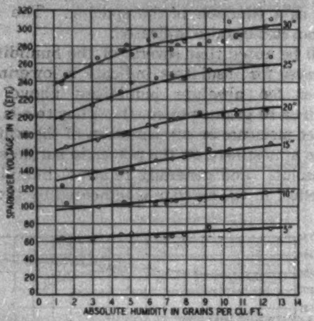

Fig. 10—Effect of Humidity on the 60-Cycle Sparkover of the Needle Gap

Air density = 1.00

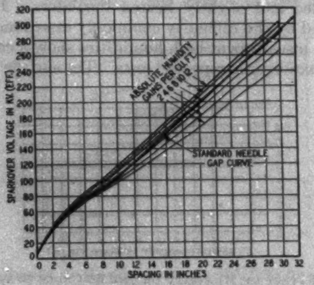

Fig. 11—Sparkover of the Needle Gap. Effect of Humidity on Sparkover. 60 Cycles

Air density = 1.00

Fig. 14 shows the effect upon the sparkover voltage of the resistivity of the water and the rate of precipitation used in making artificial rain tests on clean insulators and bushings.

That the dry 60-cycle sparkover of 10-inch diameter insulators strings having the same overall length is apparently independent of the spacing of the individual units making up those strings is indicated in Fig. 15.

Fig. 16 indicates the effect of surface dirt and moisture upon the 60-cycle sparkover of suspension insulators. The dirt used was that resulting from long exposure of the insulators to locomotive steam and smoke until the insulators were coated with a carbon deposit perhaps 1/32 to 1/16 inch in thickness. From Fig. 16 it will be observed:

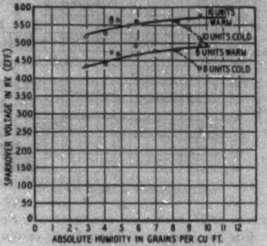

Fig. 12—Effect of Humidity on the 60-Cycle Sparkover of Suspension Insulators

10-in. diameter, 5¾-in. spacing, standard duty. Air density = 1.00

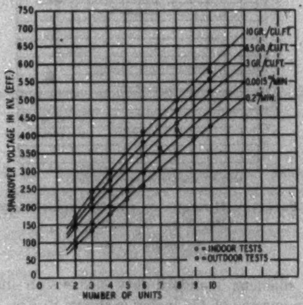

Fig. 13—Effect of Humidity on the 60-Cycle Sparkover of Suspension Insulators

10-in. diameter, 5¾-in. spacing, standard duty. Air density = 1.00

1. That this deposit of dirt when dry had practically no effect upon the insulator sparkover.

2. That the sparkover of the dirty insulators with top surface moistened was only slightly lower than the clean insulators with top and bottom surfaces moistened.

3. That the clean and dirty insulators had about the same sparkover under artificial rain conditions of 0.2

in. per minute at 45 deg. from the vertical, as specified by the A.I.E.E., presumably because some washing of the insulators took place.

4. That the dirty insulators with top and bottom surfaces moistened (by light spraying) had a very low sparkover voltage, and finally

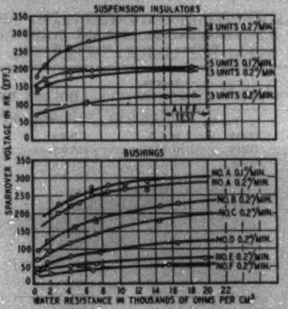

Fig. 14—Effect of Water Resistance on the Wet Sparkover of Suspension Insulators and Bushings. 60 Cycles

Air density = 1.00

5. That this latter condition combined with an atmosphere of heavy steam and locomotive smoke surrounding the string (see Fig. 17) resulted in the lowest sparkover of all. (See lowest curve in Fig. 16.)

It may be noted that under these conditions the sparkover of 14 disks was only 200 kv. effective, a reduction of 73 per cent.

Table I shows the effect of dew upon the sparkover voltage of clean and salt-coated suspension insulators.

The salted insulators in Table I were lightly coated with salt (sodium chloride) by hand-spraying with a saturated salt solution. The condensation of moisture on the porcelain surfaces was accomplished by exposure of the insulator string to the warm and somewhat humid atmosphere of the laboratory after cooling in an iced compartment. The duration of exposure in minutes is given in the table. Very little reduction in sparkover took place in five minutes. The maximum reduction was reached in about 10 or 15 minutes. The strings were observed to start to dry again after about 30 minutes of testing.

Surface moisture was found to have only a very slight effect upon the clean insulators. On the salt-coated strings a 30 to 40 per cent reduction in sparkover was common. In one case the reduction was nearly 50 per cent. The salt deposit was not excessive. Upon spraying with clean water, a salted string of nine disks would not hold 87 kv. This was a reduction of more than 85 per cent in sparkover. This reduction compares with a reduction of 50 per cent on nine disks and 60 per cent on fourteen disks for the locomotive soot-coated strings with top and bottom surfaces moistened.

Table II gives somewhat similar data on four small pin type insulators on which a deposit of mill dust had been accumulated as a result of a long time exposure in the vicinity of a Pittsburgh mill.

TABLE I—DEW TESTS ON CLEAN AND SALT-COATED INSULATORS
60 Cycles

String	No. of disks	Surface condition	Duration of exposure	Sparkover voltage	Sparkover reduction
No. 1	13	Clean and dry	0 min.	699 kv.	0 per cent
No. 1	13	Clean but moist	20 min.	692 kv.	1 per cent
No. 4	13	Salted and moist	6 min.	610 kv.	13 per cent
No. 4	13	Salted and moist	7 min.	531 kv.	24 per cent
No. 4	13	Salted and moist	8 min.	465 kv.	34 per cent
No. 4	13	Salted and moist	14 min.	425 kv.	39 per cent
No. 4	13	Salted and moist	24 min.	455 kv.	35 per cent
No. 4	13	Salted and moist	Held 127 kv. (eff.) for 7 minutes. No flashover.		
No. 4	13	String drying	31 min.	595 kv.	15 per cent
No. 4	13	String drying	44 min.	659 kv.	6 per cent
No. 5	13	Salted and moist	21 min.	466 kv.	33 per cent
No. 5	13	String drying	37 min.	594 kv.	15 per cent
No. 2	9	Clean and dry	0 min.	537 kv.	0 per cent (4)
No. 2	9	Clean but moist	6 min.	542 kv.	0 per cent
No. 3	9	Clean but moist	6 min.	300 kv. dried line unit in about 5 minutes	
No. 6	9	Salted and moist	7 min.	326 kv.	39 per cent
No. 6	9	Salted then sprayed with clean water		Less than 87 kv.	84 per cent
No. 7	5	Clean and dry	0 min.	345 kv.	0 per cent
No. 7	5	Salted and moist	6 min.	188 kv.	45 per cent
No. 7	5	Salted and moist	15 min.	175 kv.	49 per cent
No. 7	5	Salted and moist	20 min.	178 kv.	48 per cent
No. 7	5	Salted and moist	25 min.	201 kv.	42 per cent
No. 7	5	String drying	35 min.	301 kv.	13 per cent

From Table II, it may be seen that the reduction in sparkover voltage was about 66 per cent for the top and bottom moistened condition.

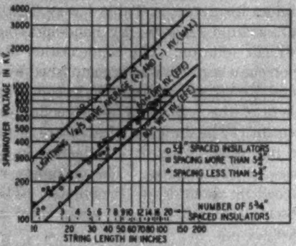

Fig. 15—Sparkover of Suspension Insulators

10-in. diameter. 5¾-in. spacing. Standard duty. Air density = 1.00

Lightning Sparkover

The effect of humidity on the lightning sparkover of different insulators is indicated in Fig. 18. Similar tests have been made on various gaps and a corresponding effect noted. Taking 6.5 grains per cu. ft. as standard, the variation in sparkover between 3 grains per cu. ft. and 10 grains per cu. ft. was found to be approximately plus and minus 10 per cent for the sizes tested. This is of the same order as the effect with 60 cycles.

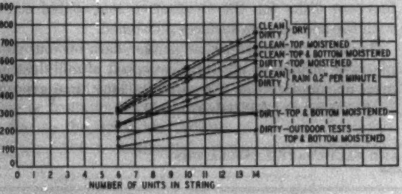

Fig. 16—Effect of Surface Moisture and Dirt Upon the Sparkover Voltage of Suspension Insulators

10-in. diameter, 5¾-in. spacing, 60 cycles. Air density = 1.00

TABLE II—60-CYCLE SPARKOVER OF DIRTY PIN TYPE INSULATORS DRY, WET AND UNDER ARTIFICIAL RAIN

Sample No.	Dry	Top surface moistened	Top and bottom moistened	Rain at 45 deg. (0.2 in. per min.)
1	58.5	29.0	19.0	27.8
2-A	59.0	33.4	23.9	25.1
2-B	58.7	26.8	25.9	27.6
3-A	59.7	32.3	21.2	25.0

Note: On the foregoing insulators with top and bottom surfaces moistened corona was visible in a darkened room at the following voltages:

sample No. 1	13.4 kv.
sample No. 2-A	10.7 kv.
sample No. 2-B	less than 9 kv.
sample No. 3	12.8 kv.

No corona was visible below 15 kv. on these insulators dry or with only the top surface moistened by spraying

That dew, fog, rain, and surface moisture have little effect upon the lightning sparkover of insulators is indicated by the data in Table III. In general, the effect of dew, fog, rain, and surface moisture decreases as the length of the wave decreases.

TABLE III—LIGHTNING SPARKOVER OF VARIOUS INSULATORS DRY AND WET

Positive Polarity Lightning Wave

Sample	Condition	Approx. wave shape	Dry	Rain 0.2 in. per min.
(a) Pin Type Insulators (Same as in Table II)				
No. 1	Dirty	0.5/5	110 kv.	106 kv.
No. 2-A	Dirty	0.5/5	113 kv.	113 kv.
No. 2-B	Dirty	0.5/5	112 kv.	109 kv.
No. 3-A	Dirty	0.5/5	122 kv.	110 kv.
(b) Pedestal Insulators				
6 units	Clean	1.5/40	1,600 kv.	1,490 kv.
(c) Suspension Insulators (Various Types)				
8 disks	Clean	1.5/40	875 kv.	845 kv.
8 disks	Clean	1.5/40	890 kv.	880 kv.
9 disks	Clean	1.5/40	945 kv.	885 kv.
12 disks	Clean	1.5/40	1,300 kv.	1,280 kv.
14 disks	Clean	1.5/40	1,370 kv.	1,310 kv.
16 disks	Clean	1.5/40	1,740 kv.	1,670 kv.
16 disks	Clean	1.5/40	1,730 kv.	1,560 kv.
18 disks	Clean	1.5/40	1,800 kv.	1,740 kv.

TABLE IV—COMPARISON OF THE DISRUPTIVE STRENGTH OF WATER AND OF AIR

Gap in cm.	Impulse kv. water	Impulse kv. air	Ratio water to air
1-Inch Diameter Spheres			
0.1	49.5	3.5	14.1
0.2	86.0	7.0	12.3
0.3	105.5	11.0	9.6
0.5	126.0	17.5	7.2
0.7	137.0	24.0	5.7
1.0	149.0	33.0	4.5
1.3	159.0	42.0	3.8
1.5	165.0	46.0	3.6
60 Deg. Points on 1/8 In. Rods			
1.0	56.5	25.0	2.05
2.0	72.0	35.3	2.15
3.0	92.0	41.0	2.25
4.0	113.0	46.5	2.42
5.0	134.0	51.5	2.61
6.0	156.0	56.5	2.76

Tests were made inside a 6-in. diameter glass sphere. Resistance of water was measured at 1.0 cm. setting of gap:

R between spheres = 20,000 ohms
R between points = 40,000 ohms

Tests on wood poles and crossarms with and without porcelain insulators mounted on the crossarm give the same indication. Wood poles, crossarms and guy insulator sticks of different cross-sectional areas have a lightning sparkover of approximately 175-kv. per ft. of length whether the wood is dry or wet with clean water or saturated salt water and brine.[8] That water has so little effect upon the lightning sparkover of porcelain insulators and insulations such as wood is probably because water is a fairly good insulator for impulse voltages as compared with air in which these materials are ordinarily tested. Table IV from "Dielectric Phenomena in High-Voltage Engineering," by F. W. Peek, Jr., Third Edition, p. 391, gives the relative disruptive strength of water as compared with air for impulse voltages.

ACKNOWLEDGMENT

Some data included in this paper have been obtained from each of the following laboratories:

High Voltage Engineering Laboratory at the Pittsfield Works of the General Electric Company.

Pittsfield Works Laboratory of the General Electric Company at Pittsfield (Outdoor and Indoor Laboratories).

Insulator Testing Laboratory at the Baltimore Works of the Locke Insulator Corporation.

FIG. 17—SMOKE TEST ON SUSPENSION INSULATORS

Switching locomotive used to supply heavily laden atmosphere of steam and smoke

The valuable assistance of the various members of the staffs of the above laboratories in making the many tests included in this paper is hereby acknowledged. The author also wishes to acknowledge the valuable guidance of Mr. F. W. Peek, Jr. under whose direction the various investigations reported above were conducted.

Discussion

For discussion of this paper see page 697.

An Improved Type of Limiting Gap
for Protecting Station Apparatus

BY A. O. AUSTIN*
Fellow, A.I.E.E.

Synopsis.—*The wide range of transients to which station apparatus is subjected is pointed out and the desirability shown for having adequate protection. The different breakdown characteristics of the various insulating members of a station are illustrated and the importance emphasized for considering this in choosing a voltage limiting device. The need is also shown for having protective gap discharges reduced to a minimum in order to limit the number of service interruptions.*

The characteristics and limitations of several forms of gaps are shown and discussed. A new form of limiting gap is described in which it is possible to change the sparkover characteristic over a considerable range to allow for the differences in time lag and polarity characteristics of station insulation. The advantage of using a limiting gap in multiple with a lightning arrester to provide maximum protection and reduce interruptions to a minimum is discussed.

* * * * *

INTRODUCTION

In the early transmission lines, comparatively little was known about the essential characteristics required in the insulation of transformers and other equipment attached to the line. In addition to this, there was no information as to the nature of transients and the number to which the station equipment would be subjected. It was clearly recognized, however, that lightning could impose stresses for which it would be impossible to provide sufficient insulation to prevent breakdown unless a safety valve were present.

It was only natural that an attempt was made to limit the voltage by the use of a discharge gap or lightning arrester. In many cases there was little difference between the protecting gap and the lightning arrester as to the ability to limit the overvoltage. It was recognized, however, that the operation of a protective gap generally caused an interruption due to the flow of normal frequency current following the high-voltage discharge. The desire to prevent the power outage following a discharge of the gap has led to many schemes for limiting the flow of current in the gap or for interrupting it.

It was recognized that the ideal lightning arrester should have a high discharge rate, small time lag, and should prevent the flow of normal frequency current, thereby giving it a great advantage over a limiting gap which would cause an interruption or material drop in voltage.

Records, as well as operating experience, show that stations may be subjected to a wide variety of transients. Although in practise it is necessary to limit the magnitude of the transients which may cause damage to the equipment, it is very desirable that any limiting device does not function unnecessarily and cause an interruption. This is particularly true where a protecting gap is used which does not have the ability to clear the line or prevent the flow of normal frequency current following discharge. This leads to the use of a limiting gap of relatively small time lag for transients of very high magnitude and steep front, in parallel with an arrester of greater time lag which will function for the many transients of lower magnitude without interrupting service.

FACTORS IN THE PROTECTION OF STATION INSULATION

It is exceedingly difficult to coordinate station insulation for the wide range of transients likely to be imposed, as the flashover characteristics may be quite different as to time lag and polarity, even though in close agreement at normal frequency. This is evident by reference to Fig. 1.

Owing to difference in time lag, a very high overpotential suddenly applied may cause one type of insulator to flash over, whereas a transient having a much lower crest value may cause another insulator to arc over. Furthermore, the difference in breakdown voltage for a negative and a positive transient may be quite large for bushings, bus insulators and the internal insulation of transformers and circuit breakers. A bus insulator or a disconnecting switch may have a high effective flashover under a negative impulse and a much lower flashover under a positive impulse. However, for some other piece of equipment, the reverse may be true. In station insulation it is therefore not only necessary to take into account the time lag in flashover, but the effect of polarity and oscillations as well.

In operation one station may be subject to very severe overpotentials, whereas the transients affecting another station may be made up largely of disturbances of lower magnitude. The transients imposed upon a given station will necessarily depend upon the storms affecting the station or the connecting lines, the number and magnitude varying greatly with the location and the line insulation.

A lightning arrester or a limiting gap which will protect station insulation against overvoltage transients has long been regarded of great economic importance, for it is evident that if a gap or lightning arrester may be depended upon to protect the insulation similar to the safety valve on a boiler, it is possible to lower the level of insulation and thereby effect a very material saving. To be fully effective, however, the limiting device must

interrupt the discharge when the overvoltage is relieved without interfering with operation.

CHARACTERISTICS OF SEVERAL FORMS OF LIMITING GAPS

Fig. 2 shows the impulse flashover values for a simple type of gap formed by two 5/8 in. rods. Fig. 3 shows the flashover characteristics for a ring gap. Fig. 4 shows the time lag characteristics for a 22-in. horn gap.

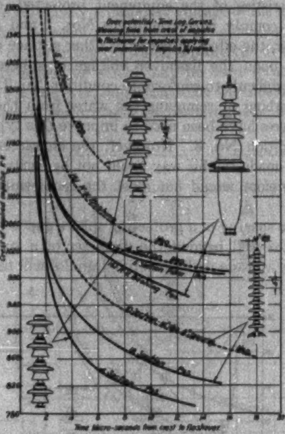

Fig. 1—Overpotential—Time Lag Curves

In considering the several types of gaps shown above, it will be noted that the flashover voltage tends to increase very rapidly for short waves or for short time intervals. Since equipment needs protection most for very severe direct strokes at or in the immediate vicinity of the station, it is evident that many gaps may not afford the desired protection, although having an arcing voltage comparatively low for less severe impulses or those of longer duration. It is also evident that the characteristics of some gaps may be widely different for a positive and a negative impulse. If the gap is to furnish efficient protection it is therefore essential that it have characteristics corresponding to those of the insulation in parallel with it, both with respect to polarity and time lag.

Fig. 5 shows the impulse time lag characteristics for a bushing and several types of limiting gaps. Typical time lag curves for only one polarity are shown in order to avoid confusion.

In order to provide protection for the bushing having the characteristics shown in curve *A*, it will be assumed that the voltage limiting gap should flashover at not more than 90 per cent of *A* for all time lags as indicated by curve *B*. The characteristic curve of the horn gap shown as *C* has approximately the same general shape as *A* for negative impulses but tends to depart somewhat for the shorter time lags. Reference to Fig. 4, however, shows that the difference between positive and negative sparkover voltages is likely to be very large for that type of gap.

By reference to Fig. 5, it will be noted that curve *D* for the ring gap intersects curve *A* at approximately 585 kv. For transients having a crest below 585 kv., the ring gap sparks over first. For transients having crest values above 585 kv., however, the ring gap does not afford protection as the bushing will arc over first. It is therefore evident that where the ring gap is set as high as possible so as to minimize unnecessary interruption for transients of lower crest and longer duration, it will afford little or no protection for severe overvoltages when most needed. To provide protection, the ring spacing and flashover voltage must be materially reduced thereby causing unnecessary interruptions. For example, the minimum flashover voltage shown in Fig. 5 for the ring is approximately 440 kv., as against 520 kv. for the bushing and a further reduction of the flashover voltage will be necessary in order to provide protection for high overpotentials.

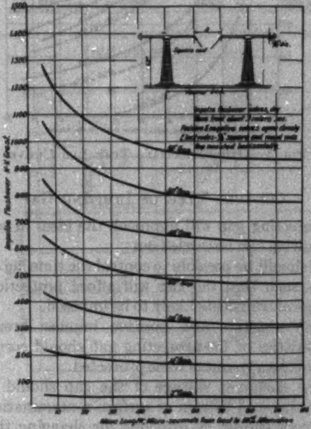

Fig. 2—Impulse Flashover Values, Dry

Curve *E* shows the characteristics of a sphere gap of negligible time lag having the same minimum flashover voltage as the gap of curve *B*. As the time of voltage application is decreased, however, insulators and most equipment will withstand much higher impulses. It is therefore desirable that the impulse flashover of the limiting gap be higher for short time lags. If a limiting gap having the rather uniform flashover characteristics of a sphere gap as shown in curve *E* is used, unnecessary flashovers will result owing to the sparkover of the gap for the shorter time lags where the insulation can well withstand higher voltages. Of course, it is possible to modify materially the characteristic of the sphere gap by changing the relative sizes of the spheres with respect to each other and with respect to the gap spacing. As will be discussed later, this principle is made use of with the control type of gap in order to obtain the characteristic of curve *A′*, Fig. 5, closely approximating the ideal characteristic curve *B*.

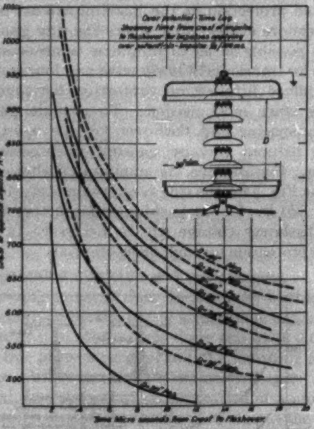

FIG. 3—OVERPOTENTIAL—TIME LAG CURVES

CONTROL TYPE OF LIMITING GAP

A protecting gap will approach the ideal in so far as the following can be carried out:

1. It should be possible to control the time lag characteristics such that the gap will afford protection over the range of transients likely to be imposed.

2. The negative and positive impulse breakdown characteristics of the protecting gap should correspond to that of the apparatus to be protected.

3. The flashover voltage of the gap should not be seriously lowered by rain or surface contaminations.

4. Means should be provided for changing the relative negative and positive flashover voltages where it is desired to work within close limits or to protect apparatus or insulation whose properties are not fully known.

5. It should be possible to change the time lag characteristics without materially affecting the minimum flashover voltage.

6. Where the discharge of the gap will cause a serious service interruption, a fuse or other device should be used for clearing the normal frequency current following discharge.

7. The gap should not discharge under high frequency wave transients of comparatively low magnitude due to switching or arcing grounds.

A gap conforming to the above requirements should have improved characteristics over types in general use in the past and a description is given below of the development of such a gap.

A protecting gap using spheres of proper size in relation to the gap spacing and of unequal diameters to provide for the difference in negative and positive characteristics of the equipment protected, could be used to comply with conditions Nos. 1 and 2 above. However, the effect of water or other surface contaminations upon the flashover voltage of spheres would make it difficult to conform to condition No. 3. Means for absorbing or removing the water from the face of the spheres have been used to improve this type of gap for condition No. 3. However, the characteristics of the gap made in this way could not be easily changed and therefore would not meet the requirements Nos. 4 and 5.

As the spacing of a protecting sphere gap is increased to lengths well beyond the diameter of a sphere, the flashover voltage under positive impulse will tend to be lower than under negative impulse. This can be offset by using a larger sphere for the live terminal and a smaller one for the ground terminal. Where the electrostatic fields of the two terminals of the gap are of equal intensity, the flashover will start from the positive terminal as it takes a lower density to start discharge with a positively charged electrode. It is therefore apparent that by controlling the flux density at the

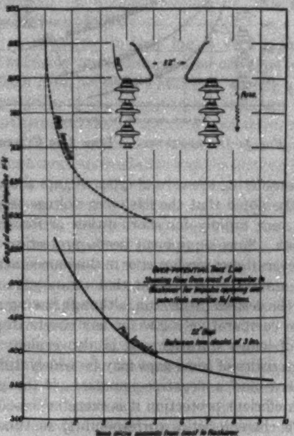

FIG. 4—OVERPOTENTIAL—TIME LAG CURVES

surface of a gap terminal, it is possible to vary the discharge voltage.

This last principle is made use of in the newly developed limiting gap, one form of which is shown on Fig. 5. The control shields shown in the vicinity of the gap terminals can be moved forward or backward to change the field density and regulate not only the time lag but the difference in negative and positive sparkover characteristics.

The results of tests in Fig. 6 show that the relative negative and positive flashover voltage of the protecting gap may be readily controlled by changing the flux density of the arcing tip which is positive. It is evident that any screen or shield may be used to accomplish this. It is however, important that the shield does not cause erratic performance by becoming one of the electrodes so that an arc will be struck between shields or between one of the tips and a shield.

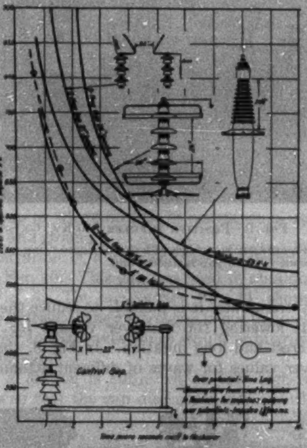

Fig. 5—Overpotential—Time Lag Curves

By using the insulated type of shield, this difficulty is prevented, even though the shields may be nearer together than the discharge points. This is particularly important under wet conditions or where the gap may be subjected to an oscillation, for under these conditions a gap having bare metal shields generally has a very low flashover voltage. Reference to Fig. 6 shows that the control of the flux density of the discharge points by means of the insulated shields is very effective in changing the relative arcing voltage for negative and positive impulse. In addition, it is seen that the arcing voltage under a damped wave or oscillation compares favorably with the arcing voltage under impulse thereby reducing unnecessary discharges.

In any discharge gap in which the electrodes are similar, the electrode or terminal on the live side generally has a much higher voltage gradient than that on the grounded side of the gap. It has been pointed out that increasing the size of this electrode would make it possible to reduce the gradient. Increasing the effective size of one electrode will also tend to increase the stress or lines of force on the electrode connected to the opposite side.

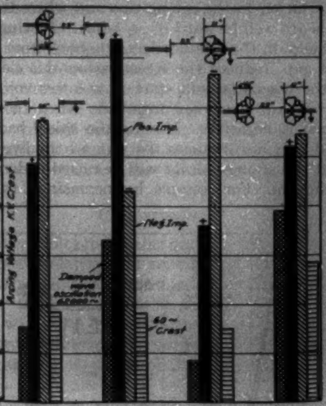

Fig. 6—Effect of Insulated Control Screens Upon Arcing Voltages of 22-In. Gap

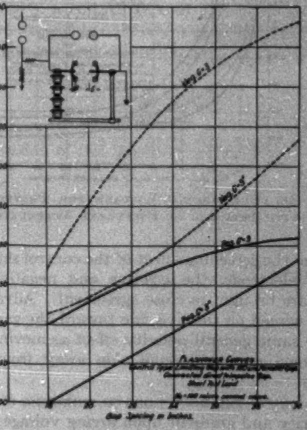

Fig. 7—Flashover Curves

Fig. 7 as well as Fig. 6 shows the change in relative negative and positive impulse sparkover values which may be effected by changing the flux density on the electrodes with insulated control shields. Reference to Fig. 7 shows that the arcing voltage for negative impulse is approximately 75 per cent greater than for positive impulse where the controlled screens have the same relation to the arcing tips and where the control screens are well forward (C = 3 in.). Moving the control shield on the ground electrode back from the point of the gap, reduces the screening on this electrode so that the discharge will start at a lower voltage for a given distance between terminals when the opposite terminal is negative. Moving the shield back on the ground side also reduces the flux on the live terminal so that the arcing voltage will be raised under the positive impulse. For example, by increasing C to 9 in. and reducing the screening effect of the control shield on the ground electrode, the positive and negative impulse values are brought in close agreement. Advancing the control screen on the live side toward the gap opening, has the same general polarity effect as moving the control screen on the ground side away from the gap opening.

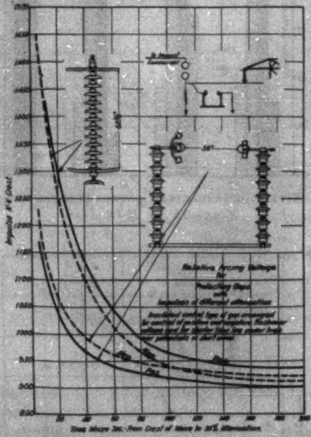

FIG. 8—RELATIVE ARCING VOLTAGE FOR PROTECTING GAPS WITH IMPULSES OF DIFFERENT ATTENUATION

The control gap allows one to make use of the effect of polarity and gradient upon arcing voltage similar to that with the point-to-plate discharge. It is evident that the arcing voltage will be increased for a given gap spacing where the stress upon the arcing tips is reduced by advancing the control shields. Therefore, by using the control shields, it is possible to reduce the gap spacing and the time lag for a given flashover voltage. It necessarily follows that the characteristics of the gap may be changed materially, both as to time lag and the effect of polarity upon discharge voltage by simply adjusting the control shields. As the projecting insulated control screen is affected but little by high frequency transients, it is possible to reduce the time lag without lowering the flashover voltage for waves of lower crest and long duration. In Fig. 8, the impulse flashover values for waves of different attenuation are given for a control type of gap and a ring equipped suspension string.

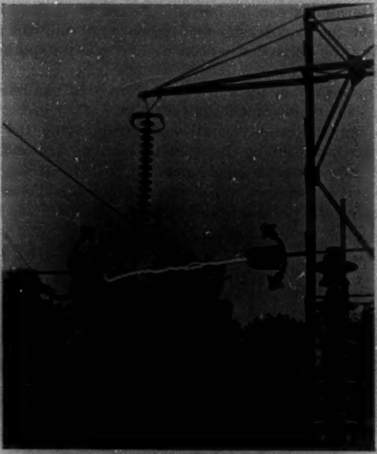

FIG. 9—POSITIVE IMPULSE 950-KV. CREST

Arcing-control gap in multiple with ring-equipped string. Wave ¼ x 100 microseconds. Control gap in artificial rain

FIG. 10—SMALLER TYPE OF CONTROL GAP

The control type of gap may be made in a number of different forms with plain shields or rings used in place of the insulated control type of screen. The latter has the advantage in that the gap does not have a low flashover value for oscillations and is affected but little by rain or conditions which may cause a gap having bare metal shield to be very erratic. Other forms of the gaps embodying the above principles may, in some cases, work out to much better advantage.

Fig. 9 shows the gap of Fig. 8 under test. The insulated support of the ground terminal may be replaced by a metal support where the change in field will not disturb the gap or where no fuse or resistance is used between gap and ground.

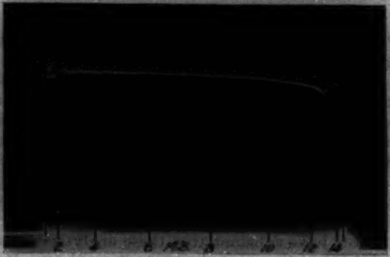

FIG. 11—NEGATIVE IMPULSE 460-KV. 1¼ x 100 WAVE ARCING 22-IN. CONTROL TYPE PROTECTING GAP

An illustration of a smaller type of control gap is shown in Fig. 10. This gap was used in obtaining the data in Fig. 5. The oscillogram, Fig. 11, shows that the arcing voltage of the control gap is not unnecessarily low even for longer waves which would ordinarily arc a horn or ring gap.

Where a station is subjected to few high-voltage transients so that the gap discharges infrequently, the clearances and setting of the gap may be of little importance, provided satisfactory protection is obtained. However, where the station must withstand many transients, it may be desirable to adjust the gap to take all discharges and, thereby, protect the equipment fully. This can only be accomplished by trial in many cases. It is therefore necessary to be able to change the sparkover characteristic of the gap.

Where the limiting gap must operate frequently some form of clearing device may be added, such as a magazine fuse or circuit breaker. In general attention should be given to the use of a lightning arrester for limiting transients without causing an interruption, using the limiting gap only where necessary to afford absolute protection or where the expense of an arrester is not warranted.

CONCLUSION

1. An ideal voltage limiting gap for station use is one wherein both polarity and time lag characteristics are capable of adjustment over a sufficient range to allow protection of all apparatus in parallel with it for any transient wave form imposed upon the station.

2. A form of limiting gap has been developed making use of adjustable electrostatic field controls for the gap electrodes. This allows the breakdown characteristics of the gap, both as to time lag and arcing voltage for positive and negative impressed waves, to be varied over a wide range so as to conform to the characteristics of the station insulation.

3. The use of a control type of gap for limiting the most severe transients only and a lightning arrester for the remainder will, undoubtedly, provide the best station protection and operation available at present.

Discussion

Suspension Insulator Assemblies

Their Design and Economic Selection

BY J. J. TOROK[*] and C. G. ARCHIBALD[†]
Associate, A.I.E.E. Non-member

***Synopsis.**—This paper presents a summary of data from extensive impulse and 60-cycle laboratory flashover tests upon suspension insulator strings relative to unit shell diameter and unit spacing. The insulating qualities and the economic advantages of the various sizes of units are discussed with due regard to the most recent lightning protection theories. Both steel tower and wood pole high-voltage transmission line insulation are given consideration from the electrotechnical and economic standpoint.*

INTRODUCTION

THE pioneer high-voltage transmission lines were insulated to the extent deemed sufficient for the normal operating voltage. The designers based their selections upon the experience gained from operating lower voltage lines. The performance of these lines is responsible to a large extent for the arbitrary quantities of insulation provided for various voltage classes. However, the average operating record of these higher voltage lines was not, in general, satisfactory. A cursory analysis of the faults and their causes showed that the majority were caused by lightning.

The formation of the majority of the lightning surges was explained at that time by the "induced voltage theory." The possibility of strokes terminating upon conductors was admitted but it was believed that these were infrequent and impossible to protect against. Several methods were tried in an attempt to reduce the lightning disturbances. At first increasing the number of suspension insulators, or "over-insulation" was tried. The resulting improvement in performance was inappreciable and not commensurate with the increase in insulation. At the same time ground wires were installed as a possible remedy. In many of these latter cases material improvement in reduction of line outages was noticed but in others no great improvement resulted. A satisfactory explanation of these apparent discrepancies did not appear until the "direct stroke" theory was proposed.[1] Following this, extensive field tests[2] were made, in which the effectiveness of ground wires and tower footing resistances were determined. Subsequent analytical studies[3-4] have disclosed the wave form and magnitude of lightning voltages which may appear across the line insulation.

With the extensive and detailed knowledge of the voltage for which a high-voltage transmission line must be insulated, the designer is now able to make a more logical choice of insulation rather than rely upon tradition. However, there are economic influences as well as electrical characteristics to be considered in the design of high-voltage lines.

STANDARDS FOR COMPARISONS

Past and present papers dealing with studies of lightning phenomena have brought us to a point where we can make a logical approach to the selection of sizes of units and their spacings in suspension insulator assemblies. In a paper presented by Messrs. Fortescue and Conwell[3] and a discussion[4] on this paper, it was shown that on a transmission line equipped with ground wires, the reflections from tower footings altered the wave form so that the resultant voltage across the insulators had the approximate shape of the wave shown in Fig. 1A. Field tests have substantiated these analytical results[4] as can be seen by comparing Figs. 1A and 1B. If the insulators are to be subjected chiefly to this type of wave it is essential to determine how the insulators will perform under these types of waves.

During the early search for the proper amount of insulation for high-voltage transmission lines, various sizes of suspension insulator units, as well as different numbers of units per string, were used over a period of a decade or more. At the present time, operating and construction companies continue to insulate their new lines with the same size units previously employed, partly because of the advantages of interchangeability and partly due to acquiescence to a standard established some years ago before the requirements for the insulation of lines against lightning were understood. In the past the actual advantage of one size over another had not been definitely established despite the multitude of sizes operating more or less satisfactorily under a wide range of conditions. Consequently, an extensive group of laboratory tests was arranged to study the effects shell diameter and unit spacing have upon the electrical and economic characteristics of suspension insulator string assemblies applicable to high-voltage service.

To make an investigation of the characteristics of insulators comprehensive, all tests should be made on a volt-time basis, that is, waves of long duration should be applied to the insulators and the magnitude varied so that flashover will take place in time lags ranging from 16 or more microseconds down to one or two. The performance of the insulation should then be judged according to its application. If it is to be used on ground wire installations the performance of the insulation should be judged by the flashover voltage at short periods of time. If it is to be used on lines not equipped

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

with ground wires its performance should be judged by long time lags as well as short. However, the majority of the transmission lines now being planned and constructed are to be equipped with ground wires. Therefore, the emphasis of this analysis will be placed on short time flashovers.

LABORATORY TESTS

Tests Establishing Comparison Basis. Laboratory tests were made upon suspension insulator assemblies and bushings with the voltage wave shown by the oscillogram of Fig. 2. This voltage wave very closely resembles the calculated curve shown in Fig. 1A. These tests were conducted to determine the relation between flashovers under this type of wave and those given by standard volt-time curves.

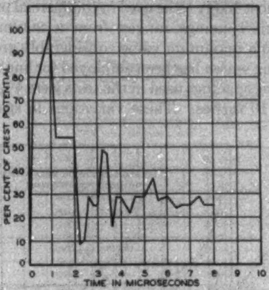

FIG. 1A—CALCULATED WAVE SHAPE

The wave shown in Fig. 2 was obtained by shunting the discharge circuit of a surge generator, arranged for the production of a smooth 1½-40 microsecond positive wave, with a needle gap having a resistance in series to ground. The needle gap flashing over near the crest of the wave results in an abrupt drop in potential across the insulators under test. However, the resistance in series with the gap limits the voltage to approximately 37 per cent of the crest voltage. Thereafter the voltage is reduced to a negligible value in five to six microseconds because of the energy dissipated by the resistor. In this manner, the wave shown in Fig. 1B was simulated.

The following crest voltages are the minimum values causing flashover of insulator assemblies made up of 8, 10, 12, and 14 units, 10-in. diameter and 5¾-in. spacing, when subjected to this type voltage wave.

No. units	Crest voltage (kv.)
8	1,050
10	1,240
12	1,550
14	1,800

It can be seen from volt-time curves shown in Fig. 5 that these voltages correspond to flashovers at some time lag lying between one and two microseconds on 1½-40 positive wave volt-time curves. The minimum flashover voltage decreases and corresponds to longer time lags when longer duration test waves are used. It has been shown in previous papers[4] that longer waves than shown in Fig. 1A result when tower footing resistances are high. These papers showed that effective ground wire protection can only be had with tower footing resistances below 10 ohms. The voltages appearing across the insulators with higher tower footing resistances become so high that it is uneconomical to insulate against even moderate intensity strokes. Because of these reasons, the comparison of insulators for use upon lines properly equipped with ground wires should be made at two microseconds as taken from volt-time curves.

It is realized that special field conditions may require a different wave upon which to base analyses; consequently, the insulator characteristic tests disclosed in this paper were made with a 1½-40 microsecond positive wave. The wave magnitude was varied to give time lag of flashover ranging from one to twenty microseconds. These results were then plotted in the form of volt-time curves. Insulator performance can be ascertained from these volt-time curves for any predetermined wave shape. In the event that some peculiar local condition necessitates the choice of an irregular wave as a basis of test, it is only necessary to test one combination of insulators with this wave. The flashover voltage values then may be referred to the volt-time curve to ascertain the corresponding time lag. The comparison of various type insulators can be made at the corresponding time lag from their respective volt-time curves.

FIG. 1B—ACTUAL WAVE SHAPE FROM FIELD TESTS

If the high-voltage transmission line is not protected by ground wires or if the ground wire protection is inadequate, then the voltage wave form across the insulators is not attended by reflections from tower footings; therefore, the wave shape approximates that of the lightning discharge. The wave form in this case is of longer duration, ranging from 10 to 50 microseconds. Since the high waves will invariably cause flashover at short time lags the impulse strength under these conditions is not important and therefore insulator characteristics should be compared under long time conditions rather than under a wave form such as shown in Fig. 1B.

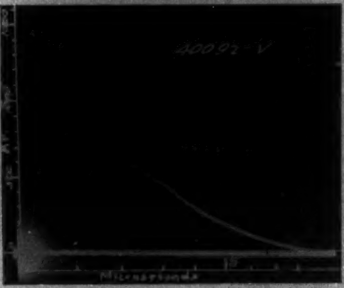

Fig. 2—Laboratory Test Wave

Diameter and Spacing Tests. Suspension insulators of the cemented cap and pin type were made up in a variety of shell diameters and unit spacings at the Westinghouse Porcelain Insulator Plant for pursuance of a series of tests to determine the effects these dimensions have upon the flashover characteristics of suspension insulator assemblies. The porcelain shells were standard in head, petticoat, and shed droop design except a special 10½-in. diameter unit designed for coastal duty. This unit had 10 per cent greater shed droop than the standard design. The heads of all these units were the same size such that all hardware was identical. This head size was that of a standard strength unit now most commonly employed upon high-voltage lines. The fixation of these details in dimension and shape limited as much as possible any variations in electrical characteristics other than those due to the unit diameters and spacings. The specific shell diameters made up for test purposes were 7, 8½, 10, 10½, 12, and 14 inches. The detail construction of the various size units is shown in Fig. 3. The design of the porcelain shells is based upon the requirements of practical application. These designs of porcelain shells are either those in common use or those most likely to be used in commercial production.

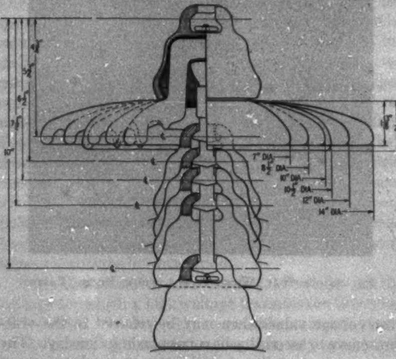

Fig. 3—Illustration of Insulators Tested

The unit spacings ranged from a minimum value possible to a maximum value considerably greater than any spacing which has been employed for line insulation. The specific spacings used in the tests were 4¾, 5¾, 6½, 7½, and 10 inches. These variations in spacing were obtained by pins of various lengths being screwed into a threaded socket provided on the stud. This arrangement materially reduced the number of units required for the tests and afforded more comparable data because identical shells of each diameter were tested at all spacings.

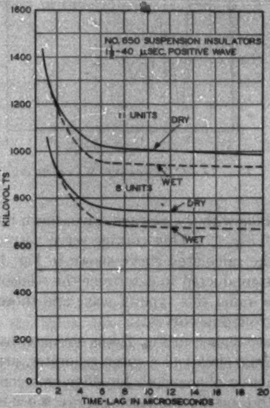

Fig. 4—Impulse Tests on Wet and Dry Insulators

Conventional 60-cycle dry and wet flashover tests were performed upon strings of 4, 8, 12, and 16 units of each dimension combination. That is, the units in each string assembly were all of the same diameter and the same spacing. No non-uniform string assemblies were tested because these conglomerations have been found to be very impractical line assemblies. These tests were made in accordance to A.I.E.E. Standard No. 41 pertaining to the conduct of normal frequency flashover tests.

Impulse flashover tests were made upon the same string assemblies with a 1½-40 microsecond lightning wave of positive polarity. A cathode ray oscillogram was made of each impulse flashover for accurate record. Over 700 oscillograph records were obtained in these tests. These data were corrected for atmospheric temperature and density, but no correction was made for the recorded relative humidity which ranged between 10 and 15 per cent. Correction factors for humidity have not been established. The question of humidity correction factors is at present before the Lightning and Insulator Subcommittee of the A.I.E.E. It is the opinion of the authors that the variation in impulse flashover voltage caused by changes in humidity during the tests is negligible. This opinion is based upon wet and dry impulse flashover tests. The average variation in time lag curves caused by standard rainfall is illustrated in Fig. 4. These curves were plotted from more than 25 points each. It can be seen that the wet and dry curves practically coincide for values less than two microseconds, and that the effects of moisture upon impulse flashover become appreciable only for time lags of three or more microseconds.

A portion of the data obtained from the impulse tests on various insulators is given in the replotted curves shown in Fig. 5. These curves were obtained from time lag curves, each of which was plotted from an average of 13 points. Some combinations of unit dimensions were not tested under the impulse wave as the test would become too long. The omitted combinations were so selected that they could be readily interpolated from the other tests. A basis for this consideration may be readily seen in Figs. 6, 7 and 8. A large number of tests upon the 14-in. diameter unit was omitted because these units were found to be impractical with present service requirements and manufacturing knowledge.

It is to be remembered that in making high-voltage measurements it is difficult to keep the limit of error

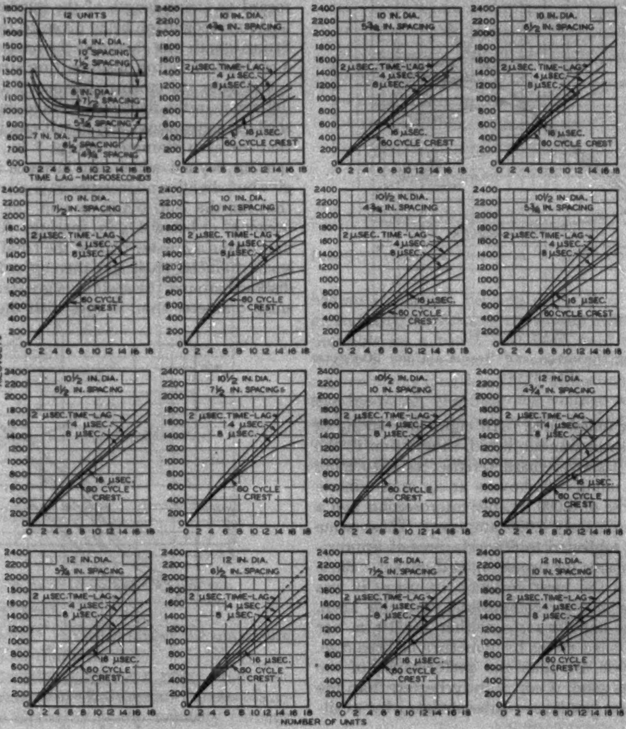

Fig. 5—Flashover Characteristics of Suspension Insulators

below about 5 per cent, even though great care is exercised. For example, on the curve showing an insulator string to have a flashover of 1,000 kv., the flashover may, under some conditions, be 1,025 or 975 kv.

The units found to be most effective under impulse tests were later subjected to arc tests to check the behavior of these diameter shells under high current impulse and power follow arcs. An eight-unit string of 12-in. diameter shells was subjected, in addition to the normal impulse flashover characteristic tests, to more than 100 severe impulse flashovers at an approximate rate of voltage rise of 6,000 kv. per microsecond and a current of approximately 5,000 amperes. These same units were then subjected to 60-cycle arcs of approximately 3,000 amperes for two seconds duration. Since the 10-in. unit is the most common in usage it was chosen as a reference for comparison with the 12-in. unit. Under the impulse tests neither the 10-in. nor the 12-in. units failed either by puncture or breakage. Under the 60-cycle arc tests the performance of the 12-in. unit was as good, if not slightly better, than the 10-in. unit. These results are substantiated by available service data.

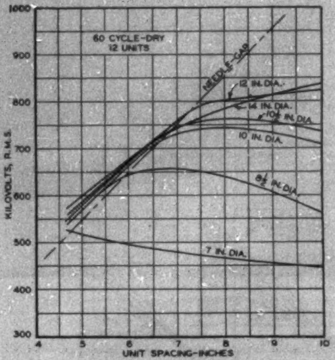

FIG. 6—EFFECT OF DIAMETER AND SPACING UPON 60-CYCLE FLASHOVER

DIAMETER AND SPACING

Impulse. The effect of unit shell diameter and unit spacing upon the flashover characteristics of suspension insulator strings is shown by representative data in Figs. 7 to 11. The economic characteristics of these factors are shown in Fig. 12. The data shown in these figures are representative in that they conform to average steel tower line conditions. A two-microsecond time lag basis of comparison is used because that value of time lag corresponds to a tower footing condition of 10 ohms or less. Higher tower footing resistances permit the lightning voltages to rise well above any economic steel tower insulation.

Figs. 6 to 10 show flashover characteristics of string assemblies consisting of 12 units. A string of 12 units was arbitrarily chosen to give a representative example of the characteristics of an insulator string with reference to shell diameter and unit spacing.

Figs. 11 and 12 show impulse flashover and economic characteristics of the various unit combinations with regard to string length of the insulator assembly itself without recognition being given to the number of units. String length was chosen as the basis of reference as it is a controlling factor in supporting structure dimensions.

60 Cycles. At normal frequency there is but slight difference in the flashover voltage due to an increase in shell diameter above 8½ in. It can be seen from Fig. 6 that for each diameter, except 7 in., there is a definite spacing beyond which any increase in the spacing will give but slight or no increase in flashover. It is probable that for the 7-in. diameter unit the knee of the curve occurs at or below 4¾-in. spacing. The head size of the unit forms a greater part of the total diameter with the small diameter shell and thereby reduces the flashover distance around the shell by a greater proportion at the small diameter than it does with the larger diameters.

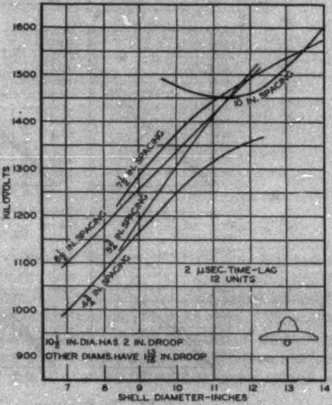

FIG. 7—EFFECT OF DIAMETER UPON FLASHOVER

It is to be noted from Fig. 6 that if the ratio of unit spacing to shell diameter is increased beyond 50 to 65 per cent, the flashover voltage falls below that of an equally spaced needle gap.

Wet flashover characteristics are of similar shape and relative position, being 60 to 75 per cent in voltage value.

It appears from Fig. 6 that at approximately 6½-in. unit spacing the 60-cycle flashover voltage will be about the same for all diameters from 10 to 14 in. Since the cost of larger diameter units is considerably higher, varying as some function of the diameter squared, it appears that large diameter units are not economical from a purely normal frequency standpoint. However, high-voltage insulation is no longer entirely judged upon its characteristics at normal frequency. The major consideration is now its behavior under impulse voltages.

Insulator Shields. The tests reported in this paper were made without auxiliary electrodes such as rings and horns. The effect of such devices has already been investigated.[11]

Cost Considerations. The designer is confronted by two major considerations in the selection of high-voltage transmission insulators. First, the permissible cost of line insulation. Second, the selection of the maximum insulation available for that cost

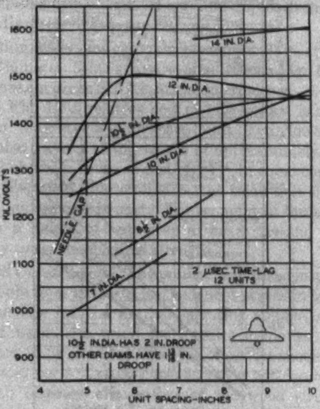

Fig. 8—Effect of Spacing Upon Flashover

The first consideration comprises many variables, such as the importance of the circuit, the necessary reliability, and the character of the territory through which the lines pass. All these factors are characteristic of each installation, and require individual study of the combination peculiar to each line. The second consideration entails the selection of the proper insulator assemblies.

Steel Construction. It must be premised that a steel tower line be properly equipped with ground wires to provide lightning protection because it is not economically feasible to protect a line by over insulating.

Once the permissible cost of insulation has been decided upon, the economic suspension insulator unit can be selected from examination of insulation and cost characteristics similar to those shown in Figs. 11 and 12.

Fig. 11 shows the impulse flashover characteristics with respect to string length of various assemblies of 10-in. and 12-in. diameter shells. These flashover voltages were taken at a two microsecond time lag for reasons described previously. It is to be noted that for a given unit spacing and flashover voltage strings comprised of 12-in. shells are appreciably shorter.

As has been pointed out previously, the string length has an important bearing upon tower design. For a given flashover voltage, the shorter string length is more desirable on a tower cost basis as it may reduce the length of the arm and the height of the tower, or, with a given string length and the utilization of a more effective insulator, the flashover voltage will be increased and the number of outages due to lightning will be decreased. For example, in Fig. 11, a 1,500-kv. flashover at two microseconds time lag is provided by a string length approximately 65 in. when composed of 12-in. diameter units spaced 4¾ in. and by a string length approximately 91 in. when composed of 10-in. diameter units spaced at 6½ in. A difference of 26 in. exists between the length of these strings. A steel tower design having the same tower clearances and height required by the long string would, of course, be appreciably heavier and more expensive than a tower designed for the short string. Using a string length of 91 in., the twelve 4¾-in. units have a flashover of 2,050 kv. as

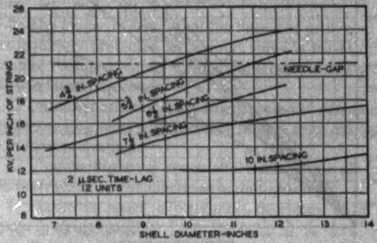

Fig. 9—Effect of Diameter Upon Flashover Efficiency

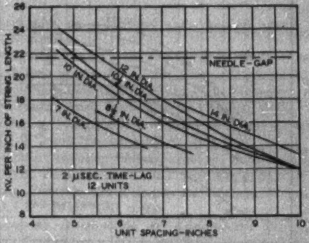

Fig. 10—Effect of Spacing Upon Flashover Efficiency

against 1,500 kv. for the ten 6½ units, or an increase of 550 kv. by using the more efficient combination of diameter and spacing. These factors should exert considerable influence upon the choice of properly dimensioned suspension units.

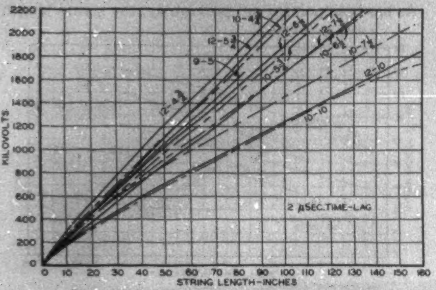

Fig. 11—Flashover Characteristics with Respect to String Length

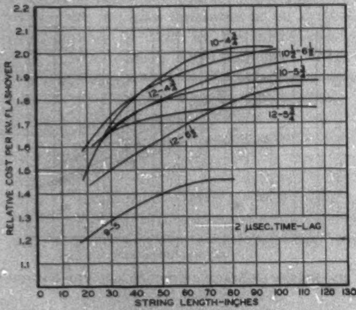

Fig. 12—Relative Insulation Cost of Various Sizes of Units

Economic Selection. The two-microsecond time lag flashover characteristics of Fig. 11 were incorporated with the cost of units to provide the economic comparison curves of Fig. 12. The cost values employed were those to a purchaser with packing and shipping expenses allowed to a shipping point 500 miles from the factory. This price is based upon the physical dimensions of the unit. The factors determining the price are, head size, shell size, and total volume, as given by the maximum dimensions of the porcelain shell. The head size determines the hardware cost factor. The shell size determines the amount of plastic material and consequently the size of moulds, etc., used in manufacturing operations. The total volume indicates the necessary kiln volume for firing, type of packing or crating, and space for storage and shipping. Fig. 12 discloses that up to approximately 70 in. string length, a 12-in. diameter unit spaced 6½ in. provides two microseconds insulation at the least insulator cost. This point corresponds roughly to the amount of insulation considered as economically balanced for 138-kv. transmission upon steel towers adequately protected by ground wires.

Beyond a string length of 70 in., a 12-in. diameter unit spaced 5¾ in. shows the lowest insulation cost. Ten-in. diameter units spaced at 4¾ or 5¾ in. are those dimension combinations most commonly used at the present time. However, these units show much higher relative costs than 12-in. diameter units at the same spacing for string lengths above 30 in. Incidentally, a string length of 30 in. corresponds roughly to economically balanced insulation commonly employed for 69 kv. Examination of these flashover and cost curves clearly indicates a wide range of selection open to a high-voltage transmission line designer for choice of the proper insulation.

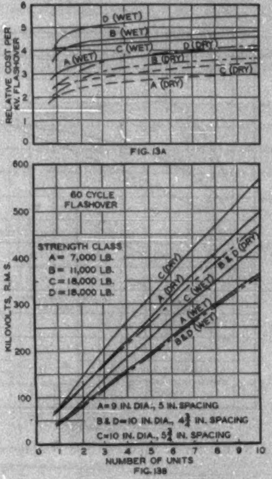

Fig. 13—Flashover and Cost Characteristics at 60 Cycles

It must be noted that Figs. 11 and 12 must be employed simultaneously to determine the maximum insulation for the least cost. For example; at approximately 65-in. string length, a 12-in. diameter 5¾-in. spaced unit provides 1,500 kv. flashover at a relative cost of 1.76, or an arbitrary total cost of 2,640, whereas a 10-in. diameter 6½-in. spaced unit to provide 1,500 kv. flashover must have a string length of approximately 91 in. This gives an arbitrary total cost of 1.93 times 1,500 which is 2,900, approximately 10 per cent higher insulation cost with 32 per cent undesirable increase in string length.

Very low cost units have been proposed for light duty purposes such as wood construction and lower voltage transmission lines. The economic characteristics of such a unit are shown by the 9-in. diameter, 5-in. spacing curve in Fig. 12. Obviously, for light duty service requiring insulation amounts corresponding to 60-in. string length (approximately 138 kv.) such units are economically desirable.

These unit dimensions were predicated upon the electrical and economic characteristics disclosed in these studies. The electrical characteristics compare favorably with those of much larger and more costly units as shown in Figs. 12 and 13. Impulse flashover string length characteristics of this unit are higher than a 12-in. diameter 6½-in. spaced unit and approach that of a 10-in. diameter 4¾-in. spaced unit.

Economically, for example, presume a 40-in. string of 9-in. diameter 5-in. spaced units. From Fig. 11 this combination gives 875 kv. at two microseconds time lag, and in Fig. 12 a relative cost of 1.35 per kv. is shown. A 12-in. diameter 5¾-in. spaced unit to provide 875 kv. must also have a string length of approximately 40 in. Fig. 12 shows a relative cost of 1.7. In equal comparison of electrical characteristics, the small unit shows a 20 per cent saving in cost. The economy of this smaller unit is a result of reduction in head size and consequently lower mechanical strength.

Wood Construction. The present practise on insulating wood pole lines is to use just sufficient porcelain to insulate the line for the normal operating voltage, and to depend upon the wood for impulse insulation. The insulator to be used for this type of service should have a low cost per kv. of 60-cycle flashover and mechanical strength slightly above that of the wood structure. Calculations of ultimate strengths of wooden structures now in use show that a unit having a mechanical strength of 7,000 lb. would be adequate. Fig. 13 shows the 60-cycle electrical and economic relationship of the various units most applicable to wood construction. The light duty unit cost is considerably below the other units, while the 60-cycle flashover per unit is only slightly below that of the popularly dimensioned unit of 10-in. diameter and 5¾-in. spacing.

CONCLUSIONS

1. The major factor of steel tower transmission line design is the shielding of the power conductors with properly located ground wires and maintaining the tower footing resistance as low as possible.

2. For towers of low footing resistance (on the order of 20 ohms) the wave is of short duration such that the minimum flashover voltage of the attached insulation corresponds to its breakdown voltage at two microseconds with a flat topped wave.

3. Suspension insulators should be judged upon their impulse flashover characteristics at two microseconds in applying insulation to well protected high-voltage lines.

4. The choice of insulation for lines not protected or inadequately protected by ground wires is based upon impulse flashover values at long time lags, of the order of 10 to 50 microseconds.

5. Impulse flashover space effectiveness of suspension insulators improves with increase in unit shell diameter at moderate spacings.

6. Impulse flashover space effectiveness for all unit diameters falls off with increase in unit spacing.

7. Flashover space effectiveness decreases with increase in string length.

8. The cost for a given impulse flashover voltage is generally lower for larger diameter units and is generally higher for larger unit spacings.

9. Available service data and laboratory tests show that the 12-in. unit is as serviceable as a 10-in. unit.

Normal Frequency Arcover Values of Insulators
as Affected by Size and Humidity

BY H. A. FREY* and K. A. HAWLEY*
Associate, A.I.E.E. Member, A.I.E.E.

INTRODUCTION

DATA covering the electrical characteristics of comparable insulators as received from different sources are frequently conflicting. A study has been made to establish rules whereby such characteristics can be estimated from the dimensions of the insulators with a reasonable degree of certainty. A long series of tests has been made covering several months with repeated checks upon the same insulator units.

The variation of dry arcovers due to the influence of humidity changes also is considered with approximate correction ratios.

The equipment used for these tests in the High Voltage Laboratory of the Locke Insulator Corporation at Baltimore consists of three transformers in cascade to give 60-cycle voltages up to 1,050,000 r.m.s. Voltages less than 350,000 were obtained by using only one of the three transformers shown in the accompanying illustration. One meter spheres were used as the primary standards for voltmeter calibration for subsequent observations. (A.I.E.E. Standard 4-53 to 57 inclusive.) The laboratory which is fully enclosed, can be kept at any desired humidity and temperature above that of the outside atmosphere. Special equipment is provided for this purpose. Routine tests upon insulators during cold weather were made at standard conditions, 25 deg. cent., (77 deg. fahr.), 65 per cent relative humidity; 0.608 in. mercury water vapor pressure. (A.I.E.E. Standard 410-100,—150). No air density corrections were made. (Standards 41-60 footnote.) Frequent calibrations from the spheres assured that insulators and sphere gaps, which are nearly equally affected by changes in air density, were under the same conditions of test. Thus insulator values were automatically referred to standard air density conditions.

TESTING EQUIPMENT—HIGH-VOLTAGE LABORATORY

Each recorded flashover measurement is the average of at least five successive arcover observations. Considerable variation was frequently noted.

TYPICAL OBSERVATION

Insulator	Pin type 35 kv. rating	Suspension 8–10 x 4¾
Total number observations	8.0	10.0
Minimum voltmeter reading	103.0	255.0
Maximum voltmeter reading	114.0	276.0
Average voltmeter reading	108.0	271.0
Per cent variation	11.0	8.2
Arcover value, kilovolts	111.0	428.0
Approximate transformer ratio	1,000 to 1	500 to 1
Barometer, inches mercury	30.14	30.01
Temperature, dry bulb	78.5 fahr.	80.0
Temperature, wet bulb	68 fahr.	68.0
Water vapor pressure	0.572	0.556

SUSPENSION INSULATORS

Tests have been made upon suspension insulators of various spacings and diameters in the vertical position. (A.I.E.E. Standard 41-150, 151.) Insulators tested are:

1. Standard strength cemented 10 in. diameter, 4¾ in., 5⅛ in., 5¾ in. spacing.
2. High strength cemented 10 in. diameter 5¾ in. spacing.
3. Extra high strength cemented 12 in. diameter 7 in. spacing.
4. Hewlett insulators 10½ in. diameter 5½ in. spacing.

The 60-cycle dry and wet flashover values of 10-in. cemented type suspension insulators of all standard spacings are shown on Fig. 1, plotted against actual arcing distance, the shortest air path between electrodes. All dry values regardless of the insulator spacing, fall upon one graph within expected errors of observation. The wet values are affected slightly by design.

The characteristics of the high strength and extra high strength insulators are shown in Fig. 2. The graph for dry measurements is identical with that for the standard insulators, Fig. 1. The wet values again show variations due to design.

The characteristics of Hewlett insulators are shown in Fig. 3. Again the graph for dry values is the same as that of Fig. 1.

Dry arcover values, therefore, for all standard insulators depend solely upon the minimum arc length or tight string distance about the insulators. The wet values

---

*Locke Insulator Corp., Baltimore, Maryland.

Presented at the Great Lakes District Meeting of the A.I.E.E., Milwaukee, Wisconsin, March 14-16, 1932.

are affected by design. In general, insulators with the greatest clear arcing distance between shells show the highest wet values. The remarkable field performance of insulators with fish tail shaped hoods even in dirty locations suggests that insulators should not be judged as much by wet values as by dry. The dry arcover values are measurably affected by the proximity of grounded objects in the neighborhood of the insulator string. This is shown by the double graph at the upper end of the dry curves. The upper graph was obtained with clearances at least twice the length of the insulator string.

The wet values of Figs. 1, 2, and 3 are plotted as a function of the overall arc length. The most usual design basis is as a function of the wet striking distance or the summation of the air gap distances beneath the insulator assuming the wetted surfaces above are short-circuited out by the water film. A more satisfactory check is so obtained as shown on Fig. 4.

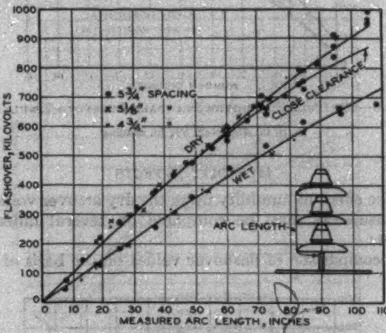

Fig. 1—60-Cycle Flashover Standard Strength Insulators 10 In. Diameter

Errors of individual observations and minor differences due to slight variations in manufacture are removed by obtaining insulator data from the above curves. Expected dry and wet arcover values of various standard and high strength insulators are given on Figs. 5, 6, and 7, plotted as a function of the number of units in the string, calculated from Figs. 1, 2, and 3.

Standard and high strength cemented insulators were tested also in the anchor position at an angle of about 10 degrees from the horizontal. The dry and wet values obtained also are shown upon Figs. 5, 6, and 7 in comparison with the arcover values for the vertical suspension insulators. The dry values are materially lower than for the insulators in the vertical. Wet arcover values are much higher in the horizontal than in the vertical. When the entire surface of the insulator is uniformily wetted a better voltage division between insulator units is obtained with the resultant higher voltage necessary to cause surface breakdown. The wet values in the horizontal are actually equal to, or in some cases with long strings, higher than the dry values in the horizontal.

Most of the tests in the horizontal were made without a jumper loop under the string or a conductor at right angles to it. Insulators in the horizontal position with the conductor at right angles showed dry values materially higher than without it, yet not equal to the values obtained for the vertical suspension insulators.

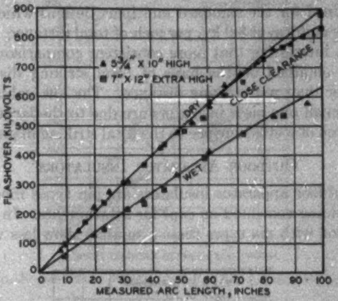

Fig. 2—60-Cycle Flashover High Strength Insulators

Pin Type (Transmission) Insulators

Standard pin type insulators show fairly uniform arcover values in proportion to the distance between electrodes as shown upon Fig. 8. The small contact area of tie wires upon the porcelain causes heavy dielectric flux concentration upon the tie wires with resultant active corona streamer formation at voltages near arcover. Observed data show least uniformity of any of the insulator types because of the erratic action of these streamers. The results of this are shown in the above tabula-

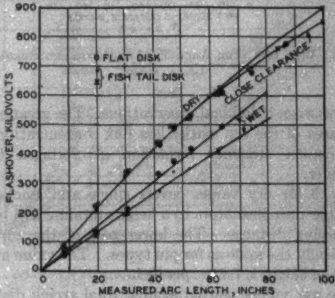

Fig. 3—60-Cycle Flashover Hewlett Suspension Insulators

tion of observed data and may be seen later on in the humidity studies. The dry flashover voltage per inch varies from 14 kv. for the small one piece and the smallest multipart insulators. It thence drops at a fairly uniform rate to 11.4 kv. for the largest multipart insulators nominally rated at 70 kv. For the single piece insulators the wet arcover value is uniformly 7 kv. per inch of total striking distance. A higher value is obtained for the standard multipart designs which are quite uniform at 8.9 kv. per inch of total distance. It is most interesting that more consistent comparisons are here obtained on the basis of total striking distance rather than wet striking distance. The low values for the small one piece insulators are due to the large proportion of wetted surface to the total striking distance.

OUTDOOR APPARATUS INSULATORS

Outdoor apparatus insulators are pin types modified by adding cemented-on caps for attachments. In comparison with pin types these insulators show less variation between individual observations. The greater contact area of the cap causes less flux concentration and less corona streamer formation at voltages below flashover.

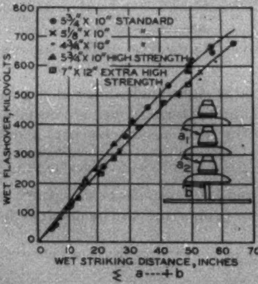

FIG. 4—WET 60-CYCLE ARCOVER ALL-CEMENTED SUSPENSION INSULATORS

Fig. 9 for dry values covers single and stacked or multiple unit insulators to a height totaling 116 inches dry arcing distance. The lower part of the curve is practically the same as for pin types. The value at 100 inches of height is 7.3 kv. per inch.

The wet values plotted against total arcing distance show considerable variation but less when plotted against the wet striking distance. Both graphs are shown on Fig. 9.

EQUIPMENT BUSHINGS, SOLID TYPE

The performance of porcelain equipment bushings (not oil filled) is shown in Fig. 10, for ratings from 7.5 to 69 kv. The field established about the bushing determines the dry values. It is important that the conductor be in place inside the insulator as it will be in service. Much higher values will be obtained without it. The wet values, however, are the breakdown voltages for the water film upon the surfaces. For the larger bushings the wet value is higher than the dry.

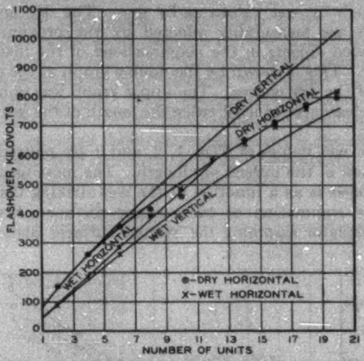

FIG. 5—60-CYCLE FLASHOVER STANDARD STRENGTH INSULATORS

10 in. diameter, 5¾ in. spacing

HUMIDITY EFFECTS

The effect of humidity upon the dry arcover voltages of insulators may be compared on several different bases:

A comparison of flashover values on the basis of per cent humidity is not satisfactory, for it alone does not account for the total quantity of water in the air.

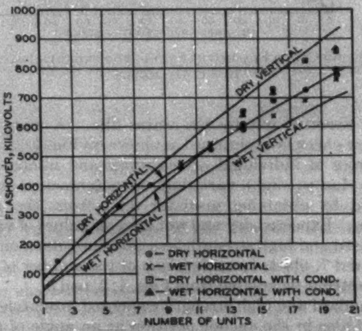

FIG. 6—60-CYCLE FLASHOVER STANDARD STRENGTH INSULATORS

10 in. diameter, 5⅛ in. spacing

A comparison on the basis of absolute humidity or mass of water per unit of air volume may be satisfactory, but does not account for the molecular activity of the water.

A comparison of flashover may be made on the basis of water vapor pressure in some convenient units such as the barometric method, inches of mercury. This not only accounts for the number of water molecules present, but their velocity as well.

The water vapor pressure as the standard is recommended by A.I.E.E. Standards (41-100). All observations in the Locke Laboratory have been compared upon this basis.

No difficulty has been experienced in maintaining the laboratory at standard temperature (25 deg. cent.—77 deg. fahr.), during the cold months. The laboratory is not equipped to reduce the temperature below that of the outside atmosphere. All tests made during the winter are at the standard temperature and with humidity adjusted as desired. In warm weather tests were made at the outdoor temperature and humidity sometimes as high as 95 deg. fahr., and 85 per cent relative humidity.

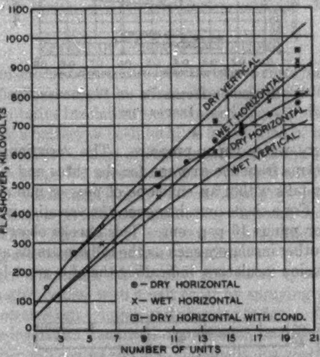

FIG. 7—60-CYCLE FLASHOVER HIGH STRENGTH INSULATORS

10 in. diameter, 5¾ in. spacing

The effect of humidity upon the dry flashover of standard suspension insulators is shown in Fig. 11. Average dry flashover curves have been drawn for strings of various numbers of units. By plotting upon semi-logarithmic paper equal ordinate distances give equal percentage variations. It is thus easy to compare percentage corrections for different strings and percentage variations from the average of individual observations.

The slope of all these average graphs is practically the same. When referred to 100 per cent at the standard water vapor pressure, 0.608 inches mercury the correction at 0.2 inches mercury is − 8 per cent. The correction, therefore, is approximately 2 per cent for each 0.1 inch of mercury variation of water vapor pressure.

The points of observation would be enclosed within an envelope of plus and minus 5 per cent from the curve of averages.

It, therefore, follows that even with the correction for humidity variations a variation of plus or minus 5 per cent in flashover values of suspension insulators must be expected. The insulators used were the same throughout the entire test.

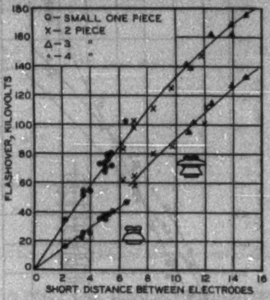

FIG. 8—60-CYCLE FLASHOVER PIN TYPE INSULATORS

The effect of humidity on flashovers of typical pin type transmission insulators is shown in Fig. 12. But one insulator of each type was tested. Variations shown are not due to manufacturing variations in different insulators. The individual observations fell within an envelope of plus or minus 6 per cent, the broadest of any insulator type tested. The variation in flashover of all insulators between vapor pressures of 0.2 and 0.608 is about 12 per cent. Frequently in testing at standard temperature with relative humidity above 65 per cent, erratic performance and marked fall in flashover was observed. A typical example is shown for the 27 kv. rated insulator. This is believed to be due to the formation of invisible water film upon the surface of the insulator at these higher humidities.

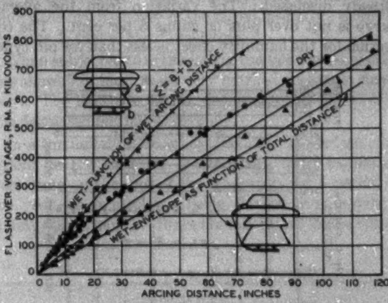

FIG. 9—60-CYCLE FLASHOVER OUTDOOR APPARATUS INSULATORS

Fig. 13 shows the effect of humidity upon typical outdoor apparatus insulators. The points of observations shown upon these graphs in comparison with those for the pin types, Fig. 12, show much more stable performance. This is due to absence of corona streamers as already discussed. The variation from the average curve is not over plus or minus 5 per cent. The correction for the humidity effect is less than for pin types.

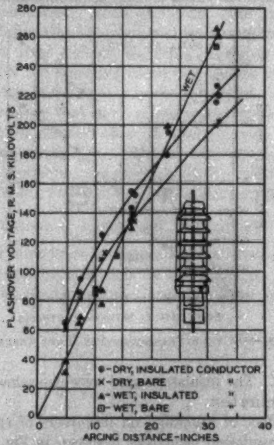

FIG. 10—60-CYCLE FLASHOVER SOLID TYPE EQUIPMENT BUSHINGS

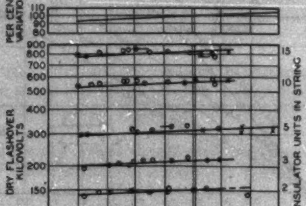

FIG. 11—EFFECT OF HUMIDITY STANDARD SUSPENSION INSULATORS

10 in. diameter, 5¾ in. spacing

It is 8 per cent between vapor pressures of 0.2 and 0.608, the same as for suspensions. Points at the upper right hand ends of these graphs are for temperatures well above standard, yet falling closely upon the same graph, indicating that comparison on the basis vapor pressures is quite satisfactory.

A most interesting observation upon an apparatus insulator of the multiple unit type for stacking is shown in Fig. 14. The correction for humidity is the same for this insulator as for the other apparatus and for the suspension insulators, 8 per cent from 0.2 to 0.608 inches mercury water vapor pressure. The variation of observations from the average for the three and six unit stacks falls within an envelope of plus or minus 5 per cent. For a single unit, however, the variation is nearly plus or minus 10 per cent. This checks observations upon other insulators such as the tall apparatus and the suspension insulators, indicating that for great lengths the percentage variations are somewhat less and the performance of the insulators more stable.

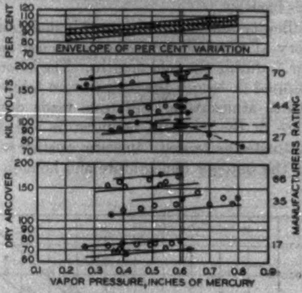

FIG. 12—EFFECT OF HUMIDITY ON FLASHOVER PIN TYPE INSULATORS

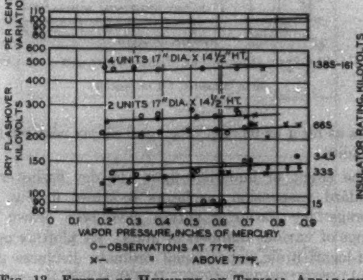

FIG. 13—EFFECT OF HUMIDITY ON TYPICAL APPARATUS INSULATORS

The performance of porcelain equipment bushings with varying humidity is shown in Fig. 15. The correction for humidity with these bushings is the same as for all others except the pin types.

A tabulation has been made, summarizing the above data as follows:

TABLE I

Insulator type	Dry value Arc length Kilovolts / Inch	Wet value Arc length Kilovolts / Inch	Wet value Wet striking distance Kilovolts / Inch	Humidity correction per 0.1 in. mercury water vapor pressure
Suspension:				
0 to 100 in.				
Standard cemented	10.5 to 9	7 to 6.8		2 per cent
High strength cemented	10.5 to 9	7 to 6.3	14 to 10.6	
Hewlett flat disk	10.5 to 9	7.5		
Hewlett fish tail	10.5 to 9	6.5		
Pin types				
Small	14	7.0		3 "
Multipart	14 to 11.4	8.9	(Erratic)	3 "
Apparatus insulators	11 to 7.3	8 to 5.7 (Erratic)	13 to 10.4	2 "
0 to 110 in. dry arcing distance				
Equipment bushings				
Solid type	13.6 to 6.75	8.3		2 "
(With bare conductor)	12.4 to 6.1	8.3		

Where two figures are given above first applies to small insulators, second to the largest with fairly uniform steps in between, except as noted as erratic.

EFFECT OF SURFACE CONDITIONS

In an effort to determine how the above rules for insulator flashover might be affected by surface conditions, representative insulators were exposed above the smoke boxes of a battery of beehive kilns for a period of several months. The surfaces of these insulators at the expiration of this period were thoroughly covered with a dirt deposit consisting largely of carbonaceous material mixed with a certain amount of clay dust and ordinary floor dirt. The coating was rather hard, due to the baking action of the heat from the kilns.

Other insulators of exactly the same type were thoroughly coated with a salt crust by spraying with a concentrated salt solution and allowing to dry.

The insulators were then flashed over, first clean and dry, then salt coated and dry, and finally dirt coated and dry. Tests were repeated with the insulators in a steam chamber filled with steam at approximately 100 deg. temperature to simulate fog conditions. Finally some of the insulators were tested under A.I.E.E. Standard Wet Flashover Test. The results of the tests are shown in the following tabulation.

It will be noted that there is very little reduction in the dry flashover of the insulators when dirty. Dry tests on the salt coated insulators were made at two humidity conditions. The first group of tests yielding the higher values in the tabulation were made at approximately 77 deg. dry bulb temperature, 65 per cent relative humidity. The second group of tests made at approximately 77 deg. dry bulb temperature and 79 per cent relative humidity gave flashover values materially lower, probably due to the absorption of water by the salt, at this relative high humidity. At the lower humidity the dry flashover of the salted insulators is nearly the same as that of clean insulators.

When subjected to artificial fog the salt coated insulators showed in most cases very marked decline in flashover. The flashover of the dirt coated insulators was also decreased but not so severely.

In a further effort to study the effect of surface conditions on the flashover of insulators, other insulators were hung on the roof of the laboratory for a period of one year, each insulator being flashed over approximately once a month. Since the laboratory is in a heavy

industrial district the insulators were subjected to soft coal smoke and industrial gas fumes. The results of the tests over a period of one year are tabulated. All flashover measurements were made at a time when the insulators were apparently thoroughly dry.

These tests were, of course, made at such humidity and temperature as happened to be existing at the time. The points have been plotted on Fig. 16. It will be noted that the curves are identical with those of Figs. 11 and 12. There are certain points on each of the curves which fall materially below the average. It is believed that in these cases the dirt film on the surface was very slightly moistened. Since most of the tests were made in the morning it is quite possible that in these cases there was still a certain amount of invisible dew remaining on the surface of the insulators.

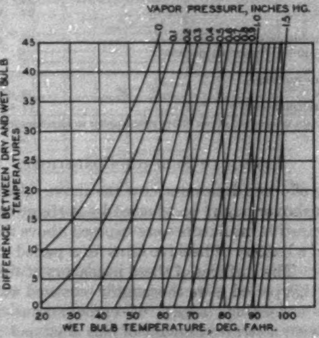

Fig. 17—Psychrometric Chart

From Smithsonian Meteorological Tables. Barometer = 30.00 in. Hg.

Conclusions

The relations found between arcing distance and insulator flashover and between humidity and insulator flashover are indicated in the foregoing curves and tabulations. At very high relative humidities there is in some cases a scattering of test results with points falling below the humidity curves. This is believed to be due

to the precipitation of a fine moisture film on the surface of the insulators.

Throughout the common range of temperatures (20 to 100 deg. fahr.) the relation between vapor pressure (expressed in manometric inches of mercury) and absolute humidity (expressed in grains per cu. ft.) is such as to make no practical difference which of them is used as the basis of measurement.

The same humidity corrections are applicable to dry dirty insulators as to clean insulators.

Dry dirt only slightly lowers the flashover of insulators. A small amount of moisture greatly reduces the flashover of dirty insulators, particularly if the dirt is of a saline nature.

At high relative humidities the flashover of salt coated insulators is materially reduced due to absorption of water by the salt.

Insulators can be checked for flashover from data given in Table I which also gives humidity correction factors. Deviation of individual flashover voltages from the average are not fully explained by humidity variations alone. After correction for humidity has been made a variation of about plus or minus 5 per cent remains in some cases.

NOTE: Vapor pressures may be obtained from barometric and dry and wet bulb thermometer readings with the assistance of the Smithsonian Meteorological Tables from which Fig. 17 has been drawn.

From this vapor pressures may be obtained with sufficient accuracy for the purpose.

NORMAL FREQUENCY ARCOVER VALUES OF INSULATORS

(FREY AND HAWLEY)

A. O. Austin: The paper by Messrs. Torok and Archibald calls attention to a subject which is of great economic importance to the transmission system. It has been evident for many years that length efficiency was frequently of far more importance than any difference in the cost of the normal insulator. With the more efficient insulator it is possible to reduce the clearances and the height of tower. In the two-circuit tower this is exceedingly important as the height of the structure can be reduced so that the probable number of hits to the line will be less. With closer clearance the line reactance is reduced and capacitance increased so that more power may be transmitted and the stability increased.

Increasing the section length or the size of the metal parts to obtain a higher ultimate without increasing the diameter and flashover voltage of the disk lowers the length efficiency of the string. Impulse tests show that the wet flashover of the string as compared to the dry flashover voltage drops off materially as the insulation of the string is reduced. The ratio of flashover voltage in the disk to the voltage imposed upon same in the string under the most severe condition is the first consideration. As an increase in diameter raises the flashover voltage it will tend to improve the string performance providing this is not offset by increased drip water and section length. It would therefore seem that insulators having higher flashover voltages than the normal 10-in. diameter disks can be used to advantage.

The 10-in. disk insulator originally had a section length of 5¼ in., a flashover voltage of 92 kv. and a mechanical ultimate of 8,000 lb. The tendency has been to increase the mechanical ultimate and section length only, and in many cases the flashover voltage probably does not exceed 70 kv. This tends to reduce the time lag and length efficiency of the string under impulse.

It is feasible to use insulators which have a higher flashover voltage even though they are considerably more expensive. Where a whole string is made up of insulators of large diameter it will be found that the drip water has a material effect upon the flashover voltage. The large projected area of the insulators increases the amount of drip water, which has a material effect upon starting a flashover under impulse. By using insulator units of large diameter along with smaller intermediate units, not only is the drip water reduced but the short-circuiting effect of the stream of drip water is much less. Strings of this kind show a greatly improved performance, and when the advantage is given due credit it will be seen that the higher cost is more than offset.

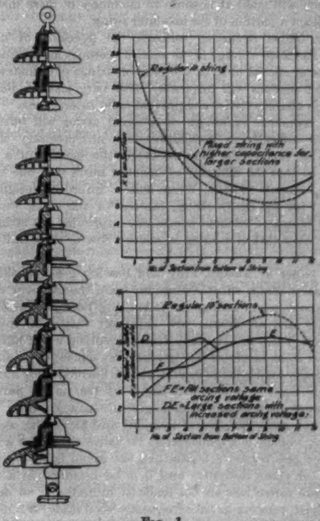

FIG. 1

The necessity of using mixed diameters in the shells of pin type insulators has long been recognized and the treatment is even more effective in the long string of suspension insulators, as accumulated drip water tends to short-circuit the lower portion of the string.

I believe that Mr. Torok should extend his investigation to include longer tailed waves, as many systems do not have a low effective ground resistance or capacitance, and an effective counterpoise may be considered too costly.

It must also be remembered that many strokes of lightning consist not of a single impulse but a number in rapid succession so that if tests are confined to a wave between one and two microseconds duration as shown by the oscillogram in the paper, the insulator may give a poorer performance in service than would be expected from the tests.

Some interesting insulators of larger diameter and higher flashover voltage were shown in a paper presented at the Pasadena Convention in 1924. Fig. 1 shows some of these insulators and the effect upon the ratio of flashover voltage to duty imposed, which may be termed the unit factor of safety. The priming or shunting of the surface insulation of the disk under a very high overvoltage makes it possible to use insulator sections of higher flashover and improved characteristics to advantage. The insertion of a few disks of large diameter in a string of short spaced 10-in. diameter units will frequently increase the flashover voltage from 15 to 25 per cent even though the insulators used do not represent the maximum possibilities as to flashover voltage.

While larger and more efficient sections have been available for many years, their higher cost has prevented their general use. Recognition of the economic advantages of the high length efficiency will make it possible to use many of these insulators for at least a portion of the insulator string.

With higher operating voltages, the necessity of using a higher flashover voltage in the section becomes more important. The use of special units at the ends of strings of ordinary 10-in. diameter sections will frequently effect very material improvements in characteristics and prevent radio interference.

The economic advantage of a mixed string will offset any assumed difficulty in installation. It is not necessary that all strings be exactly the same to obtain the benefits of a mixed string, so that the difficulty of handling more than one type of section amounts to little. While units of improved design could be used for the entire string, the cost of the string would be greatly increased without necessarily improving the string materially over that of a string in which a few of these units were used.

The paper by Messrs. Frey and Hawley gives considerable information on the effect of humidity upon the flashover voltage of various types of insulators. It has long been recognized that humidity and air density are important factors in insulator flashover. There are so many factors involved which affect the flashover of an insulator that general laws cannot be established which apply to all types of insulators. The correction for humidity therefore must be determined largely by test on the particular insulator or one approximating its general characteristics.

In many cases the effect of humidity and air density upon the flashover voltage is approximately the same as that for a needle gap. For this reason a needle gap has given fairly consistent results for many insulators and is to be preferred to a sphere gap where corrections are not made for humidity or air density. In the past, corrections have frequently been made for a measuring gap without giving the insulator the benefit of the same corrections. This practise has led to more confusion than any other item in insulator testing. In making careful dielectric tests, corrections of course should be made so as to obtain the absolute voltage applied.

As pointed out in the paper of Messrs. Frey and Hawley, the field set up by a bushing has a considerable effect on the flashover voltage. It would seem, however, that the higher wet flashover shown in Fig. 10 applies only to bushings which have a very poor surface gradient.

Many properly designed bushings have a higher flashover voltage with the conductor in place then when the conductor is removed. This is due to the fact that the design of the bushing makes use of the field set up by the metal parts in screening the surface from shunting discharge streamers.

In regard to Mr. Lloyd's paper, where the humidity is high it is very important that the insulators be at room temperature in making the tests, otherwise large discrepancies may arise.

C. L. Fortescue: It will probably take some time for the industry to appreciate the significance of the work that has been done by Messrs. Torok and Archibald. The research was started purely with the idea of finding out the influence of diameter and spacing in the impulse strength of suspension insulators. Since the object of the research was to determine the insulating value of suspension insulators of different diameters and spacings to withstand lightning surges on transmission lines it was necessary to determine only a suitable wave form to represent the actual impulsive stresses to which these insulators would be subjected under operating conditions and the wave form shown in their paper was the result.

To those not familiar with the more recent theories resulting from the lightning field investigations of the last few years I wish to point out that the direct stroke theory has been quite generally accepted by all engineers. According to this theory the outages on high-voltage transmission lines, that is to say, 66 kv. and above, are solely due to lightning strokes which hit the ground wire or line wire; the induced surge due to a nearby stroke is too low to be of any consequence. The surge that appears across an insulator when a stroke takes place at a tower is of very steep front and the high part is of very short duration. This is due to the fact that the tower itself acts as a short length of transmission line and the lightning stroke builds up the potential at the tower top during the time required to travel back to the top of the tower. The approximate wave form may easily be computed by the method of reflections and the computations result in the series of waves which was shown by the authors for different values of tower footing resistance. It will be noted that as the tower footing resistance is increased the magnitude and duration of the high part of the wave is also increased. With a very low tower footing the high part will be of low magnitude and its duration will be quite short, as short as one microsecond.

The criterion set up was the ability to withstand surges of the wave form shown and the resulting data have been given in the plotted curves in the paper. These curves show that larger diameter, namely 12 inches, and medium spacing, namely 5¾ inches, will result in the most economic insulator to apply to high-voltage transmission lines. The important gain comes about by reduction in string length which with equivalent air clearances results in a lower and cheaper tower. I wish to emphasize also that there is nothing untried in the type of insulators proposed. Insulators of this diameter and larger have been in use on the Pacific Coast and have given good service. They are just as sturdy as the standard 10-inch suspension insulator.

In discussing the Torok-Archibald paper regarding the latest point of view in the application of insulators in transmission line design, Mr. Austin has laid great stress on what might occur after flashover takes place. We prefer to lay more stress on the ability of an insulator assembly to withstand an impulse without flashing over. The protection of transmission lines is now reaching the point where the protective level is so high that more than two outages per 100 miles per year is not considered a very good record. Under such conditions it seems to me that the result of a flashover occurring once or twice on a 100-mile line per year is not of much consequence since as a general rule after the flashover occurs the line goes into service at once. A broken shed on two or three insulators is not of any great importance and the insulators can be changed at any convenient time after the occurrence of the flashover. Therefore, we are more concerned with obtaining high economic efficiency in the application of insulators than in any other feature such as what occurs after flashover takes place. We may even reach the ideal where a flashover is so rare that it may happen, due to lightning, only once in every few years.

J. J. Torok: There are two very important points in Mr. Austin's paper, first in that he points out the difference between the positive and negative flashover characteristics of various gaps and its importance in coordination, and second, the relations of flashover between waves of various durations and the volt-time curve obtained by a flat-topped wave.

Mr. Austin in his various curves points out the essential difference between the positive and negative characteristics in the volt-time curves of various forms of insulation and gaps. It is evident from these curves that careful consideration must be given to coordinate the gaps and insulators under both the positive and negative waves. At the same time he offers a possible solution to the question of gaps in coordination.

In obtaining the curves shown in Figs. 2 and 8, Mr. Austin must have spent considerable time in making the studies illustrated in these curves. The abscissa designate the time in microseconds from crest to 50 per cent attenuation. The curves vary from approximately 5 microseconds to 100 microseconds. To obtain waves of varying duration it is necessary to change the set-up for each desired wave thus making a study of this nature very tedious. Having these data it is then possible to make a comparison between curves obtained with flat-topped waves in which the magnitude is varied and the duration of the time of flashover determined and curves made with waves of varying duration. From such data it is possible to make a comparison between the flashover under waves of different duration with different times on the volt-time curve. Thus a basis of comparison of different flashovers of insulation can be established by choosing particular times on the volt-time curves.

N. B. Obbard: The paper by Messrs. Torok and Archibald is one of the first in which the economic relation of the insulator string to the cost of the tower has been taken into consideration. The usual procedure in the past has been to design the tower to suit the insulators, which have usually been designed and often purchased, before any thought is given to the towers which must support them. In its way, designing towers to suit insulators is just as incorrect, as designing insulators to fit a specific tower. The two factors, as shown by this paper, are absolutely inter-dependent, and should be considered simultaneously if the best and most economical transmission line is to be obtained.

The large clearances, high ground wire and long string lengths which are demanded by the best present day practise will increase the cost of transmission towers very considerably, unless care is taken to take advantage of the knowledge which has been recently made available to designers. The string length is a matter of particular importance in large single-circuit lines, where the center conductor must pass through the body of the tower and where it is desired to keep the outer conductors as close to the center as possible in order to reduce both torsion on the tower and right-of-way requirements.

Some recent studies showed a difference of around 10 per cent in the cost of the towers and anchors, designed for identical electrical and mechanical conditions, but with different types of insulators. It is, therefore, well worth while to consider the design of the insulators and towers at the same time and not as separate problems.

Philip Sporn: Messrs. Torok and Archibald's paper naturally falls into two parts: the first dealing with the question of the type of wave to be employed for impulse testing where the results are to be given consideration in the selection of insulators, and second, with the characteristics of insulators themselves under different arrangements of spacing and for different diameters of shells.

Regarding the question of wave shape, it is very interesting to note that the authors now believe that insulation can be compared on the basis of a single test wave (represented in Fig. 2) and this wave is substantially the same as the 1/2-5 microsecond wave of Mr. Peek. It is quite true that it is specified that this is the wave that should be used only in cases where ground resistance of the order of 10 ohms and where ground wires are employed. In this connection it is stated in the paper that if the ground wire protection is inadequate, then the wave form to be used for checking the performance of the insulators is one having a duration from 10 to 50 microseconds. I do not believe that adequate proof has been presented to justify the above statement.

The second part of the paper deals extensively with the question of diameter and spacing of insulator units. I believe that the value of this information could have been greatly enhanced if the tests had been confined to practical designs and to spacings and diameters within the commercial range. I cannot, for example, see the benefit obtained by testing 10-in. shells on 10-in. spacing that is, upon shells that have never been built for commercial use and have never really passed even the laboratory stage. There is so much more information that is badly needed now regarding the performance of standard insulators within the commercial range that it seems to me that the effort could well have been directed in those other channels with greater benefit to the industry. For example, referring to Fig. 6, it is hard to see where much more than that portion of the nest of curves between the abscissas of 4¾ and 5¾ in. can be any real value either at the present time or in the future. It is to be noted that if data within those limits are examined, and if allowance is made for the limits of test accuracy obtained, data presented in Fig. 6 will check the information presented in a number of the other papers as to the flashover value of commercial insulators when plotted against arcing instead of string length.

Referring to the impulse flashover data presented in Fig. 11, it seems to me that the weakness of the entire series of data is the fact that all the information was gathered on the basis of non-shielded strings. Within limits of spacing and shell diameter likely to be employed if grading shields were to be taken into consideration, I believe it would show that there is very little difference in flashover characteristics in a given length of distance between the rings, regardless of the insulator spacing or the insulator diameter. Beyond those limits (for example, in the case of a 10-in. shell with a 10-in. spacing, difficulties with wet flashover performance would most certainly be encountered. This, of course, is not in agreement with the statement in the paper but it is to be noted that the authors present no data to substantiate their claim.

The economics of insulator flashover per kv. is undoubtedly of importance, although quite secondary to insulator performance. I have compared the relative cost values given in the authors' Fig. 12, with insulator prices today and find there is a variation of nearly 70 per cent between insulators of different manufacture ranging in commercial size and spacing from 4¾ to 5¾-in. spacing. For the same range the authors show only a 7 per cent variation in cost. It is therefore apparent that the cost analysis made by the authors has little value except under the special conditions which they assumed in their analysis and is of very little practical importance in the selection of insulation for an actual transmission line.

In discussing wood construction, the authors state that calculations or ultimate strengths of wooden structures now in use show that a unit having a mechanical strength of 7,000 lb. would be adequate. I presume that the 7,000 lb. refers to the combined M & E test. I do not know where the authors obtained their information but there are many lines that have been built on the systems of companies with which the writer is associated where the units can be subjected to a maximum stress of 4,000 lb. M & E under class *B* loading, and we most certainly would not think of using a 7,000-lb. unit for those conditions. Nor do we believe that there will be found many other practical engineers who would be willing to sponsor construction of that type. We think that this statement discloses a total unfamiliarity with actual conditions involved in the field.

The conclusions given at the end of the paper suffer, it seems to me, from a lack of data to substantiate their validity. There is, for example, no information presented with regard to the choice of impulse waves of 10 to 50 microseconds under the conditions outlined in conclusion No. 4. Nor is any more information given to substantiate claim No. 9 with regard to the service performance of 12-in. units. While the 12-in. unit may be satisfactory, it seems to me, it is not fitting that a conclusion be established as to its adequate performance in service when not a single record is cited in the paper to substantiate it. With literally millions of 10-in. suspension insulators now in service from 5 to 17 years, ranging in spacing from 4¾ to 5¾ in. and with almost perfect performance given by these units, on a test of 90,000 units on lines of various subsidiaries of the American Gas and Electric Company where insulators have been in service from 3 to 12 years, a total of 12 bad units showed up out of the 90,000 units tested, or a little over 1/100th of 1 per cent. I think one should hesitate a great deal before changing practise on the basis of conclusion No. 9, unsupported by operating experience.

The data presented by Mr. Lloyd are very interesting in view of the fact that discrepancies in 60-cycle flashover of insulators as given by different manufacturers were pointed out forcefully in a paper* presented in New Haven in 1928. Subsequent work of the Lightning and Insulator Subcommittee has shown that this is largely due to the different humidity conditions under which the tests were made. Mr. Lloyd's paper definitely confirms this and shows how consistently the results show up when plotted against absolute humidity and not against relative humidity. The information given with regard to performance of insulators under salt spray conditions is extremely interesting as all this has been known for some time, but this is the first time that definite numerical information has been furnished. The data with regard to increased value of impulse flashover value of insulators under conditions of absolute humidity are new so far as is known, and show very definitely the need of incorporating a humidity clause in connection with any specifications for impulse value testing.

The paper by Messrs. Frey and Hawley very closely checks the information furnished by Mr. Lloyd. Mr. Hawley plots his flashover values of various insulators within the commercial range of diameter and spacing against measured arc length and it again is very interesting to note how beautifully all the data obtained fit together when plotted against this particular set of coordinates. In obtaining his information on the behavior of insulators under different humidity conditions Mr. Hawley has gone one step beyond Mr. Lloyd and has plotted his data against abscissas of vapor pressure, which is certainly the most scientific manner of presenting data, but as he points out in one of his conclusions, within the common range of temperatures it makes substantially no difference whether absolute humidity or vapor pressure is used. The information given in Fig. 10 with regard to the performance of a solid type bushing under wet and dry conditions is interesting, particularly the increased flashover obtained on higher lengths of bushing under wet conditions. This difference is probably due to a better dielectric flux distribution under the wet conditions.

W. L. Lloyd, Jr.: The front of the wave given in Fig. 1B of the paper by Messrs. Torok and Archibald and labeled "actual wave shape from field tests" is smooth and rises to its maximum in less than half a microsecond. As far as a test-piece would be concerned, the total duration of this wave from zero to maximum voltage value and then to 50 per cent of maximum on the tail of the wave is less than one microsecond. Sparkover of a test-piece takes place at or near the crest of such a wave, or not at all, and high sparkover values and impulse ratios are obtained.

The laboratory wave shown in Fig. 2 has about twice the length of front and duration of its main portion as the wave shown in Fig. 1B and this laboratory wave shape should result in lower sparkover values and impulse ratios than the actual wave shape from field tests shown in Fig. 1B. If Fig. 1B is a typical field wave, the wave in Fig. 2 should give lower values than those measured in the field. This is apparently actually the case. The voltage values given are somewhat lower than those which are generally measured with natural lightning on actual lines in the field.

The authors state that the wave shown in Fig. 2 was obtained by shunting the discharge circuit of a surge generator, arranged for the production of a smooth 1.5/40 microsecond positive wave, with a needle gap having a resistance in series to ground. The needle gap flashing over near the crest of the wave results in an abrupt drop in potential across the insulators under test. This satisfactorily accounts for the fall in voltage on the tail of the wave but does not account for the shortening of the front. Fig. 2 shows a wave having less than a one microsecond front rather than a 1.5 microsecond front. Would the authors please describe what was used to shorten the front or if this is the usual front of their 1.5 microsecond wave, data for which are given in the remaining figures of their paper. An overvoltage thrown on such a combination of discharge circuit and needle-gap with series resistance would result in a shorter front if the needle gap were to be sparked on the rising front of the wave. Fig. 2 does not indicate, however, that such was the case. Unless the capacitance of the generator used was extremely limited, sparkover took place at the point of abrupt fall in voltage indicated at approximately 1.7 microsecond. Such sparkover would not affect the front.

While the authors have made quite an extensive study of the sparkover of various spaced insulators, their efficiency and relative costs, I feel that the value of the data would have been considerably enhanced if the actual test points had been given. Without the test points on the curves, it is simply a "take it or leave it" proposition. There is no chance of gaging the accuracy of the work and therefore its value. This same comment also applies to Mr. Austin's paper, the value of which might possibly also have been enhanced if the measured test points had been given. Messrs. Hawley and Frey have given their test values in detail.

With further reference to Mr. Austin's paper, I cannot agree with all of his conclusions. Conclusions No. 1 and No. 3 give the requirements which an ideal gap should have and its use in the station. These conclusions may be proper, but in my opinion, a great many tests will be necessary before one can be certain that conclusion No. 2 is justified. So many variables enter between the different figures of this paper that it is difficult to check the data and draw definite conclusions.

I cannot agree with Mr. Austin's statement regarding the flux control gap being less erratic than the ordinary type of gap with bare electrodes. I have never heard before of the bare electrode gap being erratic when tested with *reliable equipment* under definite and known conditions.

The author states that it will be necessary to put up his type of gap and try it, and then change its characteristics, etc., until the desired characteristics are obtained. I do not think it desirable to put up a gap which must be played with. In the first place, one does not know which polarity surge will strike the station next, nor would there be time to adjust the gap if there were some way of predetermining the polarity, duration, voltage, etc. I feel that most operating engineers will want to have its characteristics more definitely known before it is placed in service as a protecting means. Many further tests will be required before we can feel that we have sufficient knowledge of the characteristics of this gap and I do not feel that the data in the paper are sufficient to prove the claims which have been made.

J. T. Lusignan: In his control type of limiting gap, Mr. Austin very ingeniously provides for a wide variation of the electrostatic field in order to secure practically any sparkover characteristic desired. In carrying this out, the following two principles are involved:

1. The effect of uniformity of voltage gradient across a gap upon the *time lag* of the gap.
2. The effect of an unsymmetrical electrostatic field upon the *polarity* at which a gap will have a lower breakdown voltage.

**Rationalization of Transmission System Insulation Strength,* Philip Sporn, A.I.E.E. TRANS., No. 4, 1928, p. 998.

Reference will be made to several simple gap arrangements to illustrate the manner in which the above time lag and polarity principles are applied.

Time Lag. The typical property of a needle gap is the non-uniform voltage distribution between electrodes as shown in *A* of Fig. 2 of this discussion. On the other hand, the sphere gap *B* is known to have a much more uniform voltage distribution across it. As a result of the higher voltage concentrations at the electrodes of the needle gap, local breakdown or corona starts there and proceeds outward long before there is any sign of breakdown in the sphere gap. Consequently, for 60-cycle voltages, or impulse voltages longer than a fraction of a microsecond, the needle gap must be set at an appreciably greater spacing for the same sparkover voltage. This increased gap length that must be broken down is an important factor in increasing the time lag of a needle gap.

For impulse breakdowns occurring in a microsecond or less, a needle gap must be set at a spacing approximately the same or smaller than that of a sphere gap in parallel with it. This is also due to the non-uniformity of field and therefore the higher time lag of the needle gap, as the following reasoning will show:

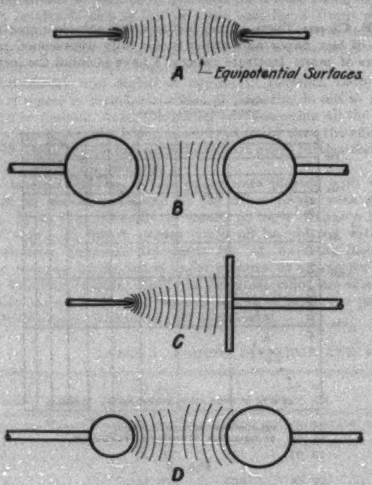

FIG. 2

When air breakdown starts at the electrodes of the sphere gap, it is only a negligible time later before the remainder of the gap is also broken down, due to the fact that practically the same voltage gradient prevails all the way across as shown in *B*. With the needle gap, on the other hand, the intense field near the electrodes causes an early failure of the air there, but until streamers from the electrodes have extended out appreciably and applied sufficiently higher voltage gradients to the center of the gap, the latter air remains undisturbed.

From the above, it is apparent that any tendency to approach a sphere gap condition by increasing the effective area of the electrodes of a gap tends to distribute the voltage gradient more evenly throughout the gap, allows the spacing to be reduced for the same sparkover voltage, and lowers the time lag. Mr. Austin accomplishes this in his control type of gap by arranging adjustable control shields about each electrode.

Polarity. It has long been recognized that sparkover between a point and a plane, as shown in *C*, always takes place at a lower value with uni-directional voltages when the point is positive; and with alternating voltages, always on a half cycle when the point is positive. In the same way the unsymmetrical field of the sphere gap *D* will cause it to display the same polarity effect and have a lower breakdown voltage when the smaller sphere is positive. The general rule for the above action is that sparkover always occurs at a lower voltage when the electrode in the more intense field is positive.

Mr. Austin develops this same polarity effect by arranging his control shields behind each electrode so as to increase or decrease its effective area and have the proper unsymmetrical electrostatic field condition across the gap.

It is apparent from Fig. 1 of Mr. Austin's paper that the insulating members of a station have line electrodes of small effective areas in comparison with the ground electrodes and, consequently, have appreciably lower positive than negative sparkover voltages. Also, Figs. 1 and 5 indicate that their time lag properties would lie between those of a needle gap and a sphere gap. With his adjustable field controls, Mr. Austin is able to secure any of the electrostatic field conditions of gaps *A*, *B*, *C* or *D* or variations of them and thereby arrange his gap to have the proper sparkover characteristics for protecting any or all station insulating members for all incoming transients, regardless of wave shape or polarity.

J. F. H. Douglas: Mr. A. O. Austin's paper shows how an analysis of the electrostatic fields can be used to achieve a sound solution of insulator problems. The different behaviour of points and spherical electrodes, with positive and negative electrification is clearly shown to be in accord with electrostatic field theory, and is verified amply by experimental test. Future experiment might be well directed toward some of the details which are not yet fully accounted for.

E. Hansson: Mr. Austin, in his paper, has outlined a method of controlling the electrostatic field around a relief gap so that the time lag of the gap will follow that of the insulation to be protected. That such coordination is necessary if full protection with a minimum of outages is to be obtained is indicated by the experience we had by reducing the line insulation ahead of some of our transformer banks.

In 1926 we reduced the insulation at both ends of two and at the station end of a third of our 66-kv. circuits from 8 to 5 units, O. B. Catalogue No. 25622. The transformer bushings which we wanted to protect were G. E. type F-1 rated at 88 kv. Our information as to the 60-cycle flashover values is 290 kv. for the bushings, and 267 kv. for the line insulators.

During 1926 and the early part of 1927, we had 22 cases of flashovers involving either bushings or reduced line insulation. Transformer bushings flashed in 7 cases, and the reduced insulation in 15 cases. Undoubtedly, the gap spacing was too large to protect the bushings under all conditions. We have no means of determining how many times the gaps operated unnecessarily. Insulation was restored to 8 units in June 1927.

Early in 1929, we installed fused arcing rings at both ends of one of the above mentioned circuits. The gap between the fuse and ring was set for 22 inches. During 1928 and 1929 we had four cases of bushing flashovers. In two of these cases, fuses were blown adjacent to the transformer and in two cases the fuses were intact.

During the same period another parallel circuit was equipped with a 12-in. gap between line and ground and in series with this gap we had an automatic fuse bank. We have had no bushing flashovers on this circuit since installation of this gap but we have, of course, blown a good many fuses. However, the fuse action is so rapid that the blowing of the fuse causes no disturbance on the system.

Joseph C. Rah: An explanation is given in the paper by H. A. Frey and K. A. Hawley that a better voltage division is obtained if the whole surface of the porcelain insulator is wetted, and therefore in the horizontal position, higher wet flashovers are obtained. This is probably true under certain conditions, but if the authors believe a better voltage distribution is obtained, then in explaining a lower wet flashover on a string of insulators by the fact that the wet surface on the top may be considered as short-circuited and only the dry air space effective, makes the two statements contradictory.

If a wet surface on the top of the insulator is short-circuited by a film of water, then the horizontally placed string will be completely short-circuited by the water film and a much lower value of flashover should be obtained, which is contrary to test results.

The results obtained on insulators from experiences of many observers, including myself, indicated that air spaces are responsible for reduced flashover rather than wet surfaces, and therefore, the wet flashovers are entirely a function of design.

Dry flashovers to a certain extent are also a function of design, as indicated by the differences in flashovers of pin type and equipment type insulators. The metallic cap on pin type insulators makes the porcelain insulator more reliable and steadier in flashover value due to a decrease in streamers, which are local flashovers. Therefore, if an insulator is designed so that streamers do not appear until up to the flashover value of the insulator assembly, then the insulator is a function of design, and not only the striking distance alone, as was proven by recent designs.

Fig. 1 gives flashovers with respect to spacings indicating that there is very little effect of spacing between disks. This may be so if the variation of spacings is one inch only where the inaccuracies of observation are great enough to offset the spacing effect. With smaller spacings however, there is a pronounced difference in flashover. The disk diameter and spacings can be adjusted to obtain well observable and definite variations in flashover values.

In the part describing equipment bushings, the authors claim that the field established around the bushing determines the dry flashover value, and by putting a conductor inside the bushing, lower flashover values are obtained.

This appears inconsistent, as introducing a conductor inside the bushing should and does improve the field, provided the interior and exterior designs are harmonious and do not interfere with one another. I have obtained flashovers considerably higher with conductors inside the bushings than without conductors with the proper exterior and interior construction.

When testing glass insulators of the same shape as porcelain, in regard to the effect of humidity, a lower flashover is obtained. This is due to the increased dielectric constant, as air nearer the insulator is overstressed. If we can lower flashover by introducing a material of a higher dielectric constant, we can also increase flashover by introducing the porcelain insulator into a humid atmosphere, which has a resultant dielectric constant higher than air, and in some cases may be higher than porcelain. This is, in my opinion, one reason of the increased flashover due to humidity. I also believe the absolute humidity is responsible for the increase of flashovers. In testing, I have found that on short insulators, the change in humidity has practically no effect on flashovers. The longer the insulator, the more effect the absolute humidity has upon flashovers. This suggests that the air is laden with moisture particles which line themselves up in the field and produce a multiplicity of condensers. This multiplicity of condensers is only effective in the part of the field which is nearly uniform. Therefore, on shorter insulators where the field is not uniform, there is little effect of the moisture particles to increase flashover potentials. On long insulators with a much longer uniform part of the field, moisture content in the air has an effect. As we increase air humidity we get more condensers in series, and therefore, the air is rendered electrically stronger until a time where there are so many moisture particles that they touch each other, and this is the dew point at which the flashover potential falls down sharply.

Corroboration of this theory may be observed in the behavior of the needle gap. The farther apart needle points are set, the larger the variation due to absolute humidity is apparent, as with increase of length the uniform field is made stronger by particles of moisture.

As far as the effect upon the sphere gap is concerned, the following may explain the apparent lack of effect of humidity. When the sphere gap is put into an atmosphere laden with moisture, the dielectric constant of the air plus the moisture is increased, and therefore the field becomes more uniform. The equipotential surfaces straighten out and instead of a sphere gap of smaller dimensions, a gap of larger dimensions is produced. If it were not for the fact that moisture is being drawn into the densest part of the field at the center line of the spheres, actual flashover of the spheres in humid atmosphere would be higher. In other words, we get a resultant strength of the air, and this resultant strength appears to be very close to the original strength of dry air.

J. E. Clem: There is one factor which enhances greatly the value of any paper and which is not fully appreciated by the authors of many Institute papers. I have in mind the inclusion of actual test points in curves. When test points are given the reader can readily form an idea of the variation to be expected in the use of the material and can also make his own analysis and form his own conclusions. I think it is almost self-evident that papers giving curves actually drawn through test points are much more valuable than those in which curves are shown but with no supporting data.

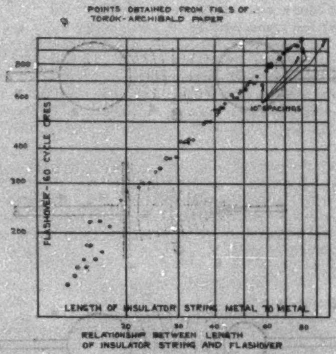

Fig. 3

The most important item of interest in the Frey-Hawley and the Lloyd papers is the effect of humidity on the flashover voltage of various types of insulators and gaps.

In Fig. 9 Mr. Lloyd shows a curve indicating that the flashover voltage of sphere gaps is not affected by changes in humidity for values of humidity of less than 11 grains per cu. ft. This is probably due to the fact that the field between the spheres is uniform and there is no point of flux concentration. It seems quite reasonable to believe that if the spacing between the spheres was large in proportion to the sphere diameter, this could no longer hold and the flashover voltage would be affected by humidity.

The type of gap which has characteristics departing most widely from those of a sphere gap is the needle gap. It would be natural then to expect that the needle gap would be greatly affected by humidity and further that needle gaps of small spacings might show less effect than long gaps. Reference to Mr. Lloyd's Fig. 10 indicates that such are the facts. Over a range of humidity from zero to 10 grains per cu. ft. the 5-in. gap increases about 18 per cent in flashover and the longer gaps increase in the order of 33 per cent over the same range of humidity.

The effect of humidity on the flashover of insulators is very important and it is also highly desirable that some standard method of making humidity corrections be made available as soon as possible. It seems reasonable to believe that insulator assemblies having a long flashover distance and having end terminals relatively small in proportion to the arcover distance, should behave approximately as a needle gap; and that small insulators should behave approximately as a sphere gap as far as the humidity effects are concerned. This is confirmed by reference to the curves in both the Frey-Hawley and Lloyd papers where humidity effects as high as 33 per cent for a long string of suspension insulators and as low as 4 per cent for a 1-unit string can be found. Fig. 12 in the Frey-Hawley paper gives an increase of about 35 per cent for pin type insulators over the same range of humidity as previously mentioned.

Unfortunately, the degree of agreement between these two papers in regard to the relative effect of humidity is not as great as could be desired. After comparing and analyzing all the data in both papers the conclusion must be reached that the effect of humidity is not completely settled and that much further thought must be given to this problem.

The humidity curves in one paper were plotted with vapor pressure as the abscissa and in the other paper with grains per cu. ft. as the abscissa. It would be very desirable if humidity curves in future papers could all be plotted with the same abscissa. Institute Standards No. 41, covering insulator testing, recommend the use of vapor pressure as a basis for comparing humidity values. Until the Institute rules are changed, and they should be if good reasons can be offered, the present Institute recommendations should be followed.

In reading through the Torok-Archibald paper one would come to the conclusion that the spacing of insulator units and the shell diameter of the insulator units have a marked effect on the flashover of an insulator string of a given length. In Figs. 1 and 2 of the Frey-Hawley paper and Fig. 15 of the Lloyd paper there are curves indicating that the unit spacing and shell diameter have very little effect on the arcover voltage of an insulator string of a given length. However, further examination of the data given in Fig. 5 of the Torok-Archibald paper leads to the conclusion that the flashover voltage of an insulator string of a specified length is approximately the same with the spacings from 4¾ to 7½ in. or with the shell diameter from 10 to 12 in.

In Table I of this discussion there is shown the 60-cycle flashover voltage of the various insulator units as read from the curves of Fig. 5 of the Torok-Archibald paper. These data are plotted in Fig. 3 of this discussion. From this figure it is seen that there is no consistent variation in flashover for varying spacings between 4¾ and 7½ in. and shell diameter between 10 and 12 in. Therefore, since the 60-cycle flashover shows no variation for these factors, it is rather difficult to understand how the impulse flashover can show any variation for the same factors, as claimed in the Torok-Archibald paper. Until sound reasons can be advanced for a difference in effect of unit spacing and shell diameter on 60-cycle and impulse flashover, extreme caution should be exercised in designing transmission line insulation based on this difference.

Fundamentally, no great difference in the flashover of an insulator string of given length for units of different spacing or different shell diameter should be expected within the ordinary limits of these dimensions. The arcing distance is the metal-to-metal length from the top of the top unit to the bottom of the bottom unit. Increasing the spacing between units increases this distance or adding a unit increases it. Whichever way the distance is increased the effect should be the same. The effect of increasing shell diameter should be greatest for a single unit. However, if the shell diameter is increased too much without increasing the thickness, no improvement would be obtained on account of the overstressing of the porcelain.

TABLE I—ARCING DISTANCE AND 60-CYCLE FLASHOVER FOR SPACING INDICATED

No. units	Dia.	4¾ in. Arc Dis.	Kv.	5¾ in. Arc dis.	Kv.	6½ in. Arc dis.	Kv.	7½ in. Arc dis.	Kv.	10 in. Arc dis.	Kv.

12		62.25	810	73.25	930						
14		71.75	920								

Based on readings from Fig. 5 of Torok-Archibald paper.

However, when the unit spacing exceeds the arcover distance of a single unit, conditions may be somewhat different. In this case each unit of the string serves as a flashover unit and there should be more liability for the strings to cascade. This is no doubt the reason for the rapid falling off in the flashover voltage of the insulators with 10-in. spacing shown in the Torok-Archibald paper.

Further evidence that the flashover of a string of insulators is independent within ordinary limits of the unit spacing or the shell diameter is given in Fig. 4 of this discussion. The plotted points represent the 60-cycle flashover of pin and pedestal type insulators. The units tested cover a wide range in design features, but it is clearly evident from the points that the total flashover voltage is a function of the total flashover length. If there were any fundamental effect on flashover voltage, of unit spacing or shell diameter, one would expect it to be as pronounced or even more pronounced in an assembly of pedestal insulators than in an assembly of suspension insulators. It seems reasonable then to conclude that within the ordinary limits of these factors there is no effect on the flashover of a string of insulators of given length whether the spacing varies from 4¾ to 7½ in. or the diameter varies from 10 to 12 in.

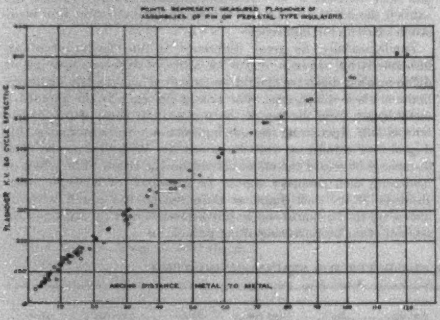

FIG. 4

In Mr. Austin's paper there is a lack of test points and oscillograms to show what impulse wave was used for obtaining the test data.

Mr. Austin would have us believe that the use of a gap for coordination leads to a very intricate and difficult problem. However, such is not the case. The problem in coordination is to select the gap setting so that the flashover of the gap will be less than the breakdown strength of the insulation for those waves which are considered most dangerous. The present tendency is to believe that the short waves of high magnitude are most likely to injure the insulation and further that there is little likelihood of obtaining long waves in sufficiently high voltage to be of much trouble. Therefore, in selecting the coordinating gap the thing to do is to base the setting on the gap characteristics for short time lags.

After comparing certain of the curves given in Mr. Austin's paper, I am doubtful as to whether his complex gap structure has any advantage over the common point gap. In Fig. 5 and Fig. 8 he shows the lag curves for the complex gap and in the text intimates that the adjustment is such as to give very desirable characteristics. For both figures about the same time lag curve could be obtained from the plain point gap, as can be verified by reference to Fig. 2 in Mr. Austin's paper. For instance, for comparison with Fig. 5, a 22-in. gap would have a flashover of about 470 at a 10 microsecond lag and about 600 at a 2 microsecond lag. Likewise for comparison with Fig. 8 a 60-in. gap would have a flashover of about 930 at a time lag of 100 microsecond and about 1,180 for 10 microsecond. It is quite clear that nothing has been gained by the use of a complicated gap structure for these two conditions.

W. L. Lloyd, Jr.: Absolute humidity may be expressed either in grains per cubic foot or in terms of the associated vapor pressure in inches of mercury. "Grains per cubic foot" appears to be the term more commonly used by engineers and it was for this reason that it was used in my paper. An absolute humidity of 6.5 grains per cubic foot corresponds to a vapor pressure of 0.608 inches of mercury at 77 deg. fahr. Therefore, where values in terms of vapor pressure in inches of mercury are desired approximate values can be obtained by dividing the grains per cubic foot by ten. The more exact figure is $\frac{6.5}{0.608} = 10.7$, but the difference in sparkover voltage associated with the resulting error in humidity value obtained is extremely small.

The A.I.E.E. Standards No. 41 dated March 1930, state that "flashover shall be determined at, or corrected to, a standard humidity corresponding to a vapor pressure of 0.6085 in (15.45 mm.) of mercury. This is equivalent to a relative humidity of 65 per cent at 77 deg. fahr. (25 deg. cent.) and a barometric pressure of 30.0 in. (76.2 cm.) of mercury." It might also have been added that this corresponds to 6.5 grains per cubic foot. In any future revision of A.I.E.E. Standards No. 41 it might be desirable to omit the reference to a relative humidity of 65 per cent at 77 deg. fahr. (25 deg. cent.) and a barometric pressure of 30.0 in. (76.2 cm.) of mercury since tests have since been made and data are given in this paper which indicate that the absolute humidity rather than the relative humidity is the determining factor.

Mr. Austin discussed the importance of maintaining the insulators at room temperature in making tests at high humidity. This is very important as indicated by Fig. 12 of my paper where a slight chilling of the insulators resulted in condensation on the porcelain surfaces and reduced sparkover voltages. Precautions against condensation were taken in making the tests up to 14 grains per cubic foot on 4 units in Fig. 3 and up to 16 grains per cubic foot on an oil-filled bushing in Fig. 8.

A. O. Austin: The several discussions make it appear that length efficiency in the insulator is a comparatively new thought, whereas the length efficiency or flashover voltage for a given length of insulator string is one of the oldest and most important considerations in the design and selection of insulators. The effect of length efficiency was treated in a paper before the World Engineering Congress in Tokio—November, 1929. Some examples showing the very material benefits possible with high length efficiency in the insulator string were treated in a paper before the International High Tension Congress in June, 1931.

Tower and conductor clearances are regarded as prime factors in transmission line costs. Unnecessary spacing not only increases the reactance of the line but increases the cost of the structure. High length efficiency in the insulator permitting of minimum tower clearance and height of structure therefore is of very great economic value. This matter was given very careful consideration by Mr. H. H. Cochrane on the lines of the Montana Power Company in 1909, the insulators and towers being selected on the basis of high length efficiency in the insulator.

Most of the work carried on at the outdoor laboratory of the Ohio Insulator Company has been devoted to increasing the flashover voltage or length efficiency of the insulator string, or in so constructing the tower as to provide maximum flashover between conductor and support. The economic advantages in many cases may be much greater than those pointed out by Mr. Obbard, particularly in the case of two-circuit towers. The use of an insulator of good length efficiency together with wood arms may double or even treble the effective flashover voltage between conductor and ground for a given vertical spacing or size of tower. Taking advantage of the high flashover voltage will permit operation at a much higher operating voltage and the increased kva. of the line may save additional circuits. Under these conditions the corona point of the conductor is likely to be the limiting factor.

The possibility of using small conductors coated with an insulating paint or varnish promises very important economic advantages where it is desired to raise the voltage of an old system or to take advantage of the close conductor spacing or the lower stress due to smaller conductors. Under these conditions the additional cost of an insulator string of increased insulation would be rather small compared to the economic advantage.

In the two-circuit tower the high length efficiency in the string permits a material reduction in the height of the tower. This results not only in a lower cost of the structure but in fewer number of probable hits to the line which should receive due credit.

More attention should be given to low effective height, not only for the conductors but for the ground wires. Shorter spans, cross connection between ground wires, and the use of increased ground capacitance or counterpoises should all be given consideration, as well as the effective flashover in the string or the flashover between the conductor and tower. Savings due to increased length efficiency in the insulator and to the increased flashover due to the use of wood arms are the most important economies to be considered at this time.

With the exception of the height of the structure, the above advantages apply to practically any transmission line even though lightning is not a consideration. The design of the transmission line is a compromise and it will be found that any method which will increase the length efficiency and flashover voltage for a given clearance will result in a material saving when applied.

In recent years there has been a tendency to develop mechanical strength in the insulator at the expense of reduced insulation in the string. It is therefore gratifying to note that length efficiency in the insulator is likely to receive some of the attention it deserves.

Mr. Sporn has raised a very pertinent question as to the maximum working load of the insulator. An insulator designed for a 4,000 lb. maximum working load will have a higher length efficiency, lower thermal stresses and a longer economic life for the same cost than an insulator designed for a 7,000 lb. maximum working load. The use of an insulator having an unnecessarily high ultimate is therefore questionable from the standpoint of economy and reliability.

Mr. Fortescue apparently has misunderstood some statement, as I have always been in favor of increasing the effective insulation as the most economical means of improving reliability rather than the use of arcing devices such as rings or horns.

The use of wood makes it possible to develop very high effective flashovers for lightning transients even for the lowest voltage and most inexpensive lines. To design station equipment so it will match the flashover voltage of the line, however, would be economically impossible particularly for the lower voltage installations. It may therefore be assumed that the station equipment will be subjected to transients which will cause flashovers or damage to some of the equipment unless the voltage is limited by an arrester or some form of limiting gap. It is much better to provide a path for the discharge which will produce little or no damage than to permit the discharge at a point where considerable damage may be caused, even though a few more interruptions may take place due to the lowered flashover value of the gap. Mr. Hansson has covered this point very effectively and shows that by equipping the gap with a quick acting fuse the discharge may have little or no effect upon the operation of the system.

A long discharge path or a resistance in series with the discharge which tends to limit the current is very effective in causing a recovery of the resistance in a discharge path. This recovery tends to prevent the follow up of a power arc and is effective in eliminating interruptions either on the line or for station equipment. Increasing the insulation level of the station decreases the probable number of interruptions, but unfortunately high insulation levels are very costly. If a high insulation level could be obtained as easily for station insulation as for the line, there would be little need of protective equipment. However, since this is impossible some device which will limit the voltage is of great economic importance particularly for the lower voltage systems.

I quite agree with Mr. Fortescue that the damage of a few insulator sections is of little moment compared to reducing the number of interruptions. However, in the case of station insulation it is frequently very difficult and costly to replace a part damaged by a power arc such as a bushing. Therefore protective apparatus such as rings or horns which lower the flashover, while being economically wrong for the transmission line, may be justified for the station.

I wish to call attention to the fact that the flashover voltage of the disk for a given section length is of far greater importance than diameter. Some of the 10-in. disks shown in the slides, which were made in 1909, have flashover values as high as 150 kv. for a 7-in. section length. An insulator string made up of these high flashover disks will have a higher insulation ratio or factor of safety than an insulator string made up of units of the same section length and a flashover value of 90 kv. even though the diameter of the sections is 14 or 15 in.

Under rain, the performance of units of larger diameter will be much poorer, particularly for an impulse having a steep wave front, comparable to a direct hit on the line.

At the present time a high length efficiency or flashover voltage for lightning can be most economically provided by a mixed string. Once the advantages of a mixed string are appreciated, it will be readily seen that these more than offset any possible disadvantages even from the maintenance standpoint, as the few replacements required could be made with either diameter of section without material effect upon the operation of the system.

In order to reduce unnecessary interruptions due to the discharge of a gap to a minimum, it is essential that the gap will not flashover under oscillations or when wet at very low values. Mr. Lloyd apparently has overlooked the fact that the flashover voltage of a horn or point gap will vary considerably under these conditions. The flashover of a sphere gap will also be influenced by water, the familiar weather protection used for sphere gaps on lightning arresters being proof of this.

Reference to Fig. 6 shows that the controls make it possible to reduce the difference in flashover voltage for various conditions, the variation being much less than for a plain point or horn gap. While the sphere gap would have less variation, the presence of water makes this gap very erratic under some transients, particularly where fairly large spheres are used.

If the station insulation has a materially higher flashover voltage with a transient of one polarity, it is possible to take advantage of this by setting the control gap accordingly, which would be impossible with other types of gaps without making a change in the parts.

In installing a control type of gap the available information of course would be used in the setting of the gap. In the case of a plain gap it would not be possible to take any advantage of the difference in flashover under negative and positive impulses, whereas the control gap could be set to take advantage of any material difference. With the control type of gap it is also possible to reduce the time lag without lowering the flashover voltage of the gap unnecessarily for low grade transients by simply adjusting the control screens and the tips.

If a plain gap is used the only change possible will be to reduce the clearance and flashover voltage. If a favorable setting is obtained when the control gap is first installed, no further change will be necessary. However if it is desired to change the characteristics of the gap to reduce the number of discharges, means are available for making this change. It is also possible to change the characteristics of the gap should the insulation of the station be changed at any time. A control type of gap certainly would require no more attention than a plain gap and even with the very meager information available it would seem that a better result would be possible without any adjusting of the gap after the initial setting.

Inability to take advantage of additional information has rendered much insulation and protective apparatus obsolete. It would seem that the possibility of taking advantage of this information certainly would not be a detriment and could not be held against the control type of gap.

The intensity and magnitude of transients may vary greatly on different systems, and there certainly is no disadvantage in being able to conform to these conditions. The polarity of a stroke of lightning of course cannot be controlled. However, if the minimum flashover voltage of the insulation is much lower for one polarity than for the other, the control gap can be adjusted for this. What is really needed is more information as to the flashover or maximum voltage which may be imposed upon the equipment. Lacking this information the control gap may be used to obtain approximate information which otherwise might not be available.

J. J. Torok: Mr. Sporn in discussing Mr. Archibald's and my paper assumes that most of the work has been confined to the short wave which he has simulated to the ½-5 microsecond wave. It was the purpose of this investigation to analyze insulator performance on a broad basis rather than any specific condition such as an investigation with a short wave. A long wave was used, commonly termed the 1½-40, and the volt-time characteristics of the insulators obtained with this wave. With such a volt-time curve the characteristics of the insulators are known for short waves as well as for long waves and an analysis of the relative characteristics of insulators can be made for any length of wave desired. Thus if it is desired the relative characteristics of the insulators can be obtained for the three preferred waves from these volt-time curves. In the paper a comparison is made using the short waves for illustrative purposes and because short waves will be encountered in ground wire installations. Also, the comparisons are made for long durations such as 60 cycles.

Mr. Sporn pointed out that the authors did not make an investigation of insulators and arcing rings. In the body of the paper the authors very explicitly stated that arcing rings were not included in these tests because the effects of rings have already been investigated and reported in other papers and that inclusion of rings would introduce such a variable as to make the data required so large as to be out of the question.

Mr. Sporn commented that the cost analysis given in the paper was at variance with present price quotations and that the discrepancy in some cases was as much as 70 per cent. The cost analysis given in the paper is based on an average cost extending over a period of five or more years and is therefore only an average cost. At present costs of raw materials and finished products are undergoing a rapid change. It is therefore to be expected that the cost of porcelain products should also change. It is very likely that at the resumption of stable prices the ratios of costs as given in the paper will be approximately correct.

Mr. Lloyd questioned the nature of the wave shape used for the short time investigation. He stated that a chopped wave should be of the saw-tooth type. The reason why this wave is of altered shape is that with such high voltages the streamer formation prior to flashover requires such heavy currents that the voltage wave is considerably distorted. In lower voltage circuits the streamer formation is considerably less and the distortion of the voltage wave is negligible.

Mr. Lloyd stated that the points should have been placed on the curves. The authors in making the curves realized that because of space limitation they would have to be greatly reduced. Consequently, the significance of such points would be lost in greatly reduced figures. Again, these points are taken from oscillograms and since the oscillograms could not be printed it was logical to draw in the curves without the points.

H. A. Frey and K. A. Hawley: We would like to point out that the humidity data contained in Mr. Lloyd's paper and that in our paper may be compared very readily since, for the practical temperatures involved, the vapor pressure expressed in inches of mercury is numerically very nearly equal to the absolute humidity expressed in grains per cubic foot. Such a comparison shows that while there are some variations which will require further study the general agreement is remarkably close.

Mr. Austin has made some statements in his discussion with which we cannot quite agree. Mr. Austin expresses the opinion that general laws for humidity correction in insulator flashover cannot be established and that such correction must be determined,—"largely by tests on the particular insulator or one approximating its general characteristics." We believe that while this opinion may be true when viewed from a strictly rigorous standpoint yet even with the data now at hand it is possible to apply a humidity correction to the flashover value of any commercial insulator which is correct to within the necessary practical limits of accuracy.

Mr. Austin also states, in commenting on certain of the bushing data, that "many properly designed bushings have a higher flashover voltage with the conductor in place than when the conductor is removed." We have experimented with *solid type* bushings of several different types and makes and have failed to find any in which the presence of the conductor did not lower the flashover value. It is quite true, however, that oil bushings with built-in flux distributors may have a higher flashover with the conductor than without. Such bushings are of an entirely different type than the solid bushings for which data are given in the paper.

The Parallel Type Inverter

BY FREDERICK N. TOMPKINS*
Member, A.I.E.E.

***Synopsis.**—The parallel type inverter is one of many forms which are undergoing development at the present time. It gives promise of becoming of considerable importance and therefore the principles of operation should be better and more widely known. The object of this paper is to make a qualitative analysis of the operation of this type under different conditions of loading, and to present the results largely in the form of complete sets of oscillograms for further study.*

Inverters of the types now being studied involve the use of hot-cathode mercury-vapor tubes called thyratrons. The characteristics of these tubes are given briefly and the data necessary for an understanding of their operation in these circuits are presented.

The principle of operation of the inverter circuit is developed by means of simple diagrams and then the actual conditions throughout the circuit are studied by means of oscillograms showing the voltages and currents in all of the essential parts. It is shown that the method of operation may be considered in a different manner from that usually assumed in the development of the circuit, inasmuch as the capacitor can be thought of as performing the function of giving the correct phase relation between the input current and the induced transformer primary voltage, rather than providing a sudden reversal of potential on the anode of the tube being stopped. This reversal is provided by the induced primary voltage. The current conditions for the various steps of operation are shown by simple diagrams.

The effects of low power factor loads with both leading and lagging current are shown in sets of oscillograms taken under these conditions. Another oscillogram gives the effects of improper circuit constants when operating at low power factor.

The output wave form under conditions of full load, unity power factor, is analyzed and it is shown that with the proper circuit constants the voltage wave is a fair approximation of sine wave. The output wave forms change, for any given set of circuit constants, with the character and degree of loading.

When reasonably good output wave forms are secured, the voltage regulation is poor but the efficiency is high. Changes in the circuit which give better regulation cause poorer wave form so that in the design of this type of inverter circuit a balance must be chosen between these two factors. Curves of efficiency and regulation, the latter showing the effects of different values of capacity, are given and briefly discussed.

INTRODUCTION

THE development of the thyratron or three-element, hot-cathode gas-filled tube has given electrical engineering a new tool. Many interesting and valuable applications have been devised, among the most interesting of these being the inverter. Its purpose is the inversion or changing of direct current to alternating current, the reverse process of the more usual rectification. The inversion process is possible with the ordinary types of three-element vacuum tubes, but due to their low efficiency and high voltage drops it has not been practical to secure alternating current in this manner. With the advent of the thyratron, with its high efficiency, low voltage drop, and its ability to handle comparatively large amounts of power, the inverter gives promise of becoming of commercial importance. Hitherto, inversion from direct to alternating current has been possible only by means of rotating machinery. If the inverter is successfully developed, as it seems to give promise of being, a method of inversion will be provided which does not require rotating machinery, but which accomplishes its purpose by means of starting and stopping electron flows. This operation can be performed at high voltages, thus making high-voltage direct-current power transmission possible, the energy being generated as alternating current, rectified to direct current for transmission, and then inverted to alternating current at the receiving end of the line. It is easy to conceive of many other interesting applications of this circuit.

Inverter circuits may be divided into two main types, series and parallel. While considerable data have been published and many different circuits devised for the former type, very little beyond the fundamental circuit has been given for the latter. The purpose of this paper is to present the results of a study of the parallel type inverter which was undertaken to secure a better understanding of the function of each part and the operation as a whole. There is presented the necessary information concerning the operation of thyratrons in order that their operation in the circuit may be understood. The principles of operation of the inverter are developed by means of simple diagrams, and the actual operation under various conditions of loading is shown and discussed from complete sets of oscillograms. It is shown that the function of the condenser in the complete circuit may be considered to provide a phase relation necessary for operation, thereby differing from the description of its function that has hitherto been made. The regulation and efficiency will be indicated and briefly discussed.

THYRATRON CHARACTERISTICS

It is beyond the province of this paper to cover completely the characteristics of the thyratron but since the operation of the inverter cannot be understood without a knowledge of these, the essentials are given. Various types of thyratrons have been developed differing in their characteristics. The technical information concerning the more common and smaller types is listed in Table I. Much larger thyratrons than those listed are made for greater plate currents and higher anode voltages.

The thyratron, being a grid-controlled arc in low-pressure gas, differs considerably in operation from the

Deionization time (Microsec.)	1,000.0 approx.	1,000.0 approx.	100.0 approx.

ordinary vacuum tube. The characteristics essential for an understanding of its operation in the inverter circuit are given below.

1. The thyratron is a gas-filled tube dependent upon ionization of the gas by the passage of current to remove the space charge, thus allowing large currents to flow with very small and nearly constant tube voltage drops and consequently having a high efficiency with high anode voltage.

2. The potential of the grid controls the starting of the tube, but when the current has started and the gas has become ionized the grid has no further control. The grid has no control over the stopping of the flow of current nor of the amount of current flowing. The potential of the grid which will allow the current to start or that will prevent it from starting is dependent upon a number of factors, among them being the anode voltage, the temperature of the tube, and the inherent characteristics of the tube. Inverter tubes usually require the grid to be positive before the current will start.

3. Flow of current through the tube may be stopped in either of two ways; the anode may be made negative, causing the current to cease, deionization to take place and the grid to resume control, or the plate current may be momentarily interrupted giving the same effect. When alternating current is applied to the anode it becomes negative each half cycle, thus giving the first condition, and returning control to the grid each cycle. With direct current applied to the plate its potential must be made momentarily negative or the current interrupted for a sufficient length of time for deionization to take place before the grid can resume control.

4. The amount of current passed through the tube is dependent upon the characteristics of the external circuit, the average tube voltage drop of the order of fifteen volts having little effect. The safe amount of current is determined by the voltage drop across the tube and is limited by destructive ionic bombardment of the cathode. It has been found that as long as the current passed through the tube does not exceed the emission of the cathode, destructive bombardment will not take place.

The thyratron is inherently a rectifier, passing current in one direction only, thus it is often convenient to think of the device as a one-way contactor with an average drop of 15 volts irrespective of the amount of current. This view will help in the understanding of the operation of the inverter.

FUNDAMENTAL CIRCUIT

The development of the inverter from simple circuits involving direct-current-operated thyratrons has been described by several writers on the subject. A similar method will be used here with the aid of simple diagrams. The connections shown in Fig. 1 are indicative of a means of stopping the current in a direct-current-operated thyratron by momentarily making the anode potential negative. A condenser *C* is connected in series with a resistance across the load. The grid of the tube is normally biased negatively, thus no current can pass. If a positive impulse is applied to the grid circuit sufficient to overcome the bias the current will start. The grid has now lost control as the gas is ionized by the passage of the current. Assuming 500 volts being supplied, the drop across the load will be 485 volts as the tube drop is approximately 15 volts. The condenser being across the load will be charged at this potential. Now assume the switch *S* is closed; the right hand side of condenser *C*, which was at a positive potential of 485 volts, is suddenly dropped to zero volts. Due to the transient impedance of the load the left hand terminal of the condenser momentarily undergoes a similar drop which brings the anode potential to the value of 470 volts negative. If this negative voltage is maintained for a sufficient length of time, deionization takes place, the current is stopped, and the grid again assumes control.

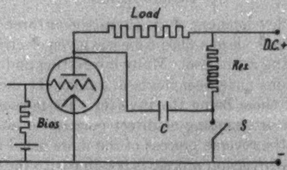

FIG. 1—METHOD OF STOPPING A THYRATRON OPERATED ON DIRECT CURRENT

First stage in inverter operation

The next step in the development of the inverter circuit is the substitution of another thyratron for the switch. The connections are shown in Fig. 2. Here the grids are shown connected to a transformer in such a manner as to cause them to be alternately positive and negative. If the grid of No. 1 tube is positive, current will be passing through it and through the load, No. 2 tube not operating because its grid is negative and the conditions will be the same as in the previous discussion with the switch open. Now as the grid potentials change, that of No. 1 will become negative, which will have no effect upon it, while that of No. 2 will become positive. As the potential applied to the anode of No. 2 is positive, current will flow through this tube and the conditions will be the same as in Fig. 1 with the switch closed, except that there is a tube drop of 15 volts. If the same supply potential is assumed as for the first case, the left hand terminal of condenser *C*, instead of falling to zero volts, now falls to positive 15 bringing the anode potential of No. 1 tube to 465 volts negative. Tube No. 2, it is seen, has performed the same function as the switch in Fig. 1. If the grids are made alternately negative and positive the current may be transferred back and forth between the two tubes, the major requirement for the operation being that the anodes are negative for a sufficient length of time for deionization to take place.

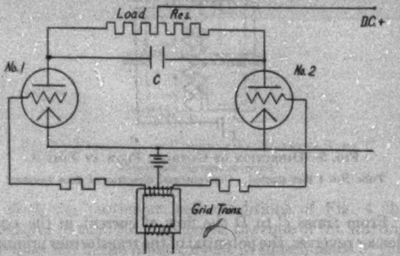

Fig. 2—Method of Stopping a Thyratron Operated on Direct Current by Means of Another Thyratron

Second stage of inverter operation

Substituting for the load and resistance of Fig 2, the primary of a transformer, gives the fundamental circuit of the parallel type inverter. This is shown in Fig. 3 with the addition of a choke coil in the supply lead to keep the alternating-current component out of the direct-current circuit. The actions taking place in this circuit are considerably more complicated than those in the circuit of Fig. 2, due to the addition of an inductance coil, the leakage reactance of the transformer, and the fact that considerable capacitance must be used. Another factor, which was not present in the circuit of Fig. 2, is the induced voltage of the transformer primary which greatly affects the operation of this circuit. A bias battery is shown so connected that the grids are biased negatively, but experience indicates that this is not needed. The frequency of the output is determined by the frequency applied to the grid transformer, which in this case is shown supplied from an external circuit. It is possible to make the circuit self-exciting, in which case the frequency is governed by the constants of the grid circuit.

OPERATION

The sequence of events in the operation of the circuit is illustrated by the oscillograms of Fig. 4 which give the voltages and currents in the different parts at approximately full-load unity power factor. In the tests herein described FG-67 inverter tubes were used, the condenser capacity being 4.5 μf., the inductance being 0.2 h., and the applied voltage of the order of 500 volts. While with this applied voltage the peak-inverse and peak-forward voltages were, under some conditions, rather more than the values given in the tube rating, no trouble was experienced from this cause. The circuit constants were chosen after much experimentation to give the best output wave form under widely varying conditions of load regardless of other factors such as regulation. In taking the oscillograms the input voltage was adjusted until the output voltage was 110, the grid voltage frequency being 60 cycles. The connection diagrams associated with the oscillograms of Fig. 4 show the positions of the oscillograph galvanometer elements in the circuit, and the various curves are numbered accordingly. The results are purely qualitative as no attempt was made to calibrate the elements.

It may now be of interest to analyze the conditions in each part of the circuit step by step throughout the cycle of operation. Referring to Fig. 4 at time *A*, curve 1 shows that the grid potential was zero, which at the applied plate potential was sufficient to permit the plate current to start as shown in curve 2. The condenser immediately charges through half of the primary in the transformer as shown in curves 3 and 4. The current in this half would have become zero except for this charging current. The current in the other half of the primary, which was slightly negative, becomes positive as shown in curve 5. A high potential difference between the anode and cathode of the tube drops to a low value as soon as the current starts, as shown by curve 7, the anode being positive. This tube voltage drop of between 10 to 24 volts does not show on the oscillograms as the scale required by the inverse voltage was too

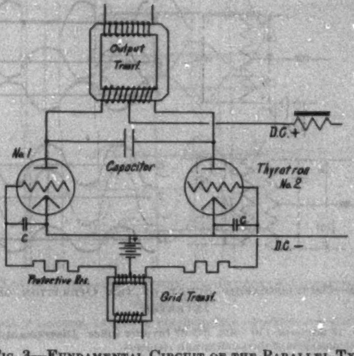

Fig. 3—Fundamental Circuit of the Parallel Type Inverter

large. The curves of 8, 9, 10 and 11 are the voltages of the halves of the transformer primary, the whole primary, and the secondary. The current in curve 12 is the output current which, when compared with the voltage of curve 11, shows that the load was non-inductive. The flow of current in the circuit an instant after time *A* is illustrated by Fig. 5, the arrows indicating the direction of flow from positive to negative according to the usual manner.

At time *B* the transformer primary and secondary voltages and the output current are zero. Comparing these with curve 2 indicates that this condition does not exist until some time after the current through the tube has started, thus showing that the latter leads the induced voltages. This is a characteristic of this type of inverter that will be found throughout its operation and it is the function of the condenser in the circuit to provide this phase relation. It will be shown later that when the power factor of the load is sufficiently leading the condenser is no longer needed, the necessary phase relations for inverter operation being caused by the load.

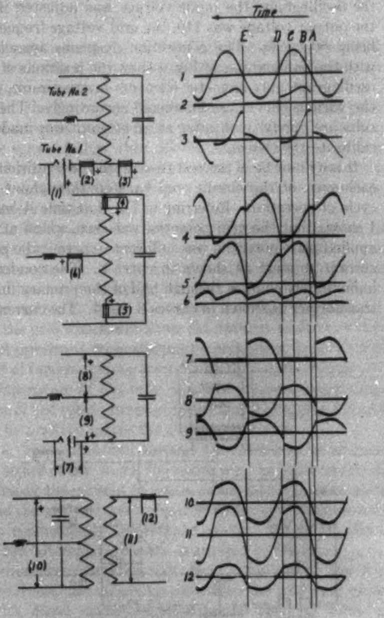

FIG. 4—OSCILLOGRAPHIC STUDY OF THE OPERATION OF THE INVERTER

Load, 18 amperes, 110 volts, FG-67 inverter tubes. Diagrams at the left show the positions of the oscillograph elements

Time *C* is interesting as at this time the flow of current into the condenser has stopped as indicated by curve 3, and consequently the current through one-half of the primary has also stopped as shown in curve 4. It is also noted from curves 8, 9, 10, 11 and 12 that at this time the transformer voltages and output current are at nearly their maximum value. The current flow conditions at this time are illustrated in Fig. 6.

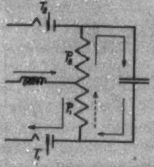

FIG. 5—DIRECTION OF CURRENT FLOW AT TIME *A*

Tube No. 1 just started. Conventional direction of flow assumed

From times *C* to *D* the flow of current in the condenser reverses, the potential of the transformer primary falling, thus leaving the condenser at a higher voltage; this flow of current naturally follows. The reversal of current in the condenser is shown in curve 3 and the consequent reversal of current through one-half of the transformer primary in curve 4. This reversed current continues until the other thyratron starts. The current conditions at this time are shown in Fig. 7.

Time *D* illustrates the stopping of thyratron No. 1 and the starting of No. 2. Curve 1 shows that when the grid of No. 2 becomes zero, current starts to pass through this tube, the flow through thyratron No. 1 stops as indicated by curve 2 and the condenser charges in the reverse direction as shown by curve 3. Curve 7 indicates the negative potential which appears between the anode and cathode of No. 1 thyratron which permits deionization to take place. The time that this anode remains negative is given by the distance between the sudden negative drop to the place where the curve again crosses the zero line in the positive direction. This time, while short, is long enough for the gas content of the tube to become deionized as this requires only approximately 100 microseconds for the tubes being used. From the time of starting of the other

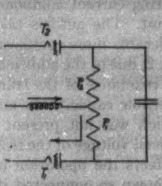

FIG. 6—DIRECTION OF CURRENT FLOW AT TIME *C*

Condenser fully charged

tube the conditions in the circuit are similar to those already described, tube No. 2 replacing No. 1 and the other half of the transformer primary carrying the tube current. It is seen that only half of the primary is active at a given time as far as output is concerned. This fact must be taken into account when choosing the transformer ratio desired for an inverter circuit. The current conditions at time *D* are illustrated by Fig. 8.

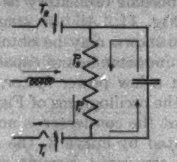

Fig. 7—Direction of Current Flow After Time *C*

Condenser current reversed

With the particular load conditions of Fig. 4 the stopping of tube No. 1 occurs at the time of the starting of tube No. 2, the input current in consequence of this action not reaching zero as shown by curve 6. With other conditions of load one tube stops conducting some time before the other starts, as shown by the other sets of oscillograms. The stopping of current flow through the thyratrons can be explained in a different manner than was assumed in the description of the development of the inverter circuit as the condenser may be thought of as performing a different function in the complete circuit. It is seen that the potential of half the transformer primary is shown in curve 9, the anode end being negative to the center when the tube is operating and positive when no current is passing. Voltage only appears between the cathode and anode on the oscillograms under the condition of no current flow, the tube drop being too small to show. If due to the starting of tube No. 2 there was a sudden change in voltage across the condenser terminals it would appear in curve 10, but there is no evidence of such change. The method of stopping the operation of one tube when the other starts in the case of the conditions shown in Fig. 4 may be analyzed as follows. Just an instant before time *D*, tube No. 1 is conducting as shown by curve 2 and the voltage of its half of the primary is shown by curve 9. At time *D* the grid of tube No. 2 becomes zero, which is sufficient to allow it to start carrying current, the anode potential being positive as is seen in curve 8. When this occurs the full potential of the primary less the tube drop of No. 2 is impressed on tube No. 1, the cathodes, being connected together, completing the circuit. This action causes the cathode of No. 1 tube to become for a time more positive than its anode, thus stopping the current flow. The voltage impressed on this tube is shown in curve 10. The anode remains negative to the cathode for a sufficient length of time for deionization to take place, and when it does become positive the grid potential is sufficiently negative to prevent the current from starting. From this analysis it follows that the action of the condenser is to give the correct phase relations for operation, which differs from the earlier conception of its purpose in the description of the development of the circuit.

Tube No. 2 starts conducting, tube No. 1 stops

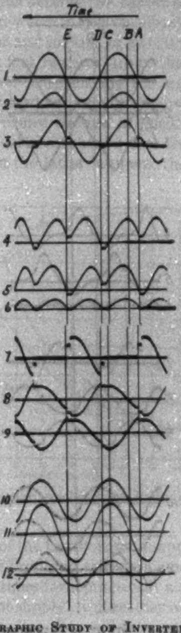

Fig. 9—Oscillographic Study of Inverter Operation at Light Load

Output, 5 amperes, 110 volts, non-inductive. Positions of oscillograph elements as in Fig. 4

Oscillograms for light-load operation are shown in Fig. 9. It is seen that the shapes of the curves are in many cases greatly altered, and that the output waveform is better. An analysis of the operation in this and in succeeding sets of oscillograms does not differ materially from that just made. In the case just discussed one thyratron stopped only when the other started. Curve 2 of Fig. 9 shows that No. 1 tube stops before No. 2 starts. This is apparently due to the constants of the whole circuit including the load. When this happens the anode potential becomes negative due to the potential of one-half of the primary coil, the latter being shown by curve 9 and the sudden drop to this value appearing in curve 7. When the second tube starts putting the full primary potential on the first tube, the anode potential becomes still more negative as shown by the second drop in curve 7. In other words, the anode voltage becomes practically first that of curve 9 and then that of curve 10.

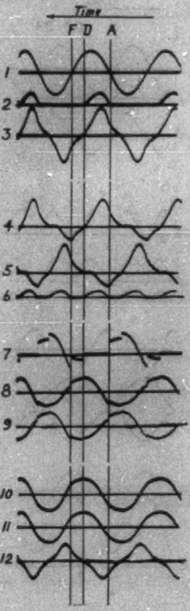

Fig. 10—Oscillographic Study of Inverter Operation with Inductive Load

Output, 19 amperes, 110 volts, 11.5 per cent power factor, condenser 6¾ μf., inductance 0.20 h.

Low Power Factor Loads

The parallel type inverter will carry low power factor loads when the circuit has the proper constants. An example of the operation with lagging current is given in the oscillograms of Fig. 10. The output voltage and current, curves 11 and 12, show that the current was lagging and that the power factor was very low. In this case, as in the case just described, the current through one tube stops some time before that through the other starts. This operation is characterized by the two distinct negative voltage drops appearing between the cathode and anode of the stopped tube as shown by curve 7.

With incorrect constants and low power factor loads the circuit may become oscillatory as is shown in the oscillograms in Fig. 11. All the stages from correct operation to that shown may be obtained by varying the values of the inductance and capacity.

Operation with a low power factor, leading-current load is shown in the oscillograms of Fig. 12. It is interesting to note that the condenser is not needed in this case, as is indicated by curve 3, the necessary phase relation between the input current and the induced primary voltage being caused by the load. The fact that this circuit will operate under this condition is proof that the condenser is needed only to give the necessary phase relation and not to fulfill the function assumed in the development of the circuit.

Fig. 11—Output with Inductive Load, Incorrect Circuit Constants

Wave Form

The output wave forms differ with the amount and power factor of the load when fixed values of capacity and inductance are used. With unity power factor, the best wave form is given at light load but as this is not as interesting a condition as full load, it was the wave form of the latter which was analyzed. When the curves for analysis were obtained the output voltage was not held at 110 volts as was done previously. The results of the analysis are given in Table II.

Regulation and Efficiency

The value of the capacitor used in the circuit has great bearing on the voltage regulation of this type of inverter. It also has a large effect on the output wave form so that a reasonable compromise must be made. A low capacity gives the best voltage regulation and the poorest wave form and may cause instability. Capacity of too large a value reduces the output voltage to a considerable extent.

The efficiency of the inverter using thyratrons is high due largely to the high efficiency of the tubes them-

TABLE II

Effective voltage	122 volts
Average voltage	115 volts
Form factor	1.06
Peak factor	1.30
Maximum value of the 3rd harmonic	16.75 volts
Maximum value of the 5th harmonic	6.35 volts
Maximum value of the 7th harmonic	2.80 volts
Maximum value of the 9th harmonic	1.18 volts

selves. With an average tube voltage drop of only 15 volts and with reasonably high anode voltage, the losses in the tube are small and the efficiency high. Fig. 13 shows efficiency and voltage regulation curves in which it is seen that the regulation with 4½ μf. capacity is much poorer than with 1⅛ μf. However, to secure a reasonably good output wave form it was necessary to use the higher value.

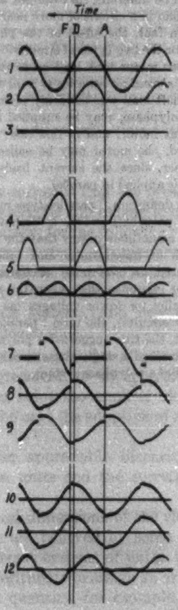

Fig. 12—Oscillographic Study of Inverter Operation with Capacitative Load

Output, 18 amperes, 110 volts, 10.1 per cent power factor, no condenser, inductance 0.20 h.

Conclusions

The oscillograms give in a graphical way the complete operation of the inverter under widely varying load conditions. An analysis indicates that the operation differs somewhat from the descriptions previously made, and it is felt that a more complete picture of the functions of each part and of the operation as a whole is here presented than has hitherto appeared. The circuit is a most interesting one and already has been applied in a commercial way for supplying alternating-current power to alternating-current radio sets where operation on direct-current distribution systems is required.

Nothing has been said about parallel operation of inverters with systems supplied by synchronous machines. This is a perfectly feasible method of operation and has the advantage that no condenser is required in the inverter circuit, thus making the operation more stable.

The two factors which may give difficulty are the poor voltage regulation and the lack of stability under certain conditions. The first requires, up to the present time, that some method of regulating the input voltage be used. The second, which largely disappears in parallel operation, will require the use of quick acting circuit breakers to protect the tubes in case the circuit stops operating. When the latter happens, the counter electromotive force of the transformer disappears, and both the tube voltage drop and the resistance of the circuit being small, the tubes form practically a short circuit on the direct-current supply. Unless they are very quickly removed from the line they will be injured.

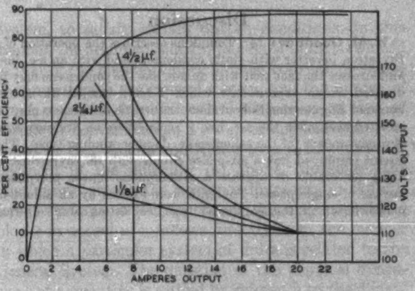

Fig. 13—Efficiency and Voltage Regulation Curves

There is nothing to indicate that the difficulties of operation are insurmountable, and since the growth of electrical engineering seems to be in the direction of an increasing use of thermionic devices it may be expected that circuits of this nature will rapidly become of commercial importance.

Discussion

W. M. Goodhue: Mr. Tompkins describes the operation of a thyratron inverter with static condensers and with an a-c. line, and stresses the fact that with an a-c. line the condensers may be omitted. Some experiments which I have carried on at the Harvard Engineering School show that static condensers may be omitted also when the a-c. line is replaced by an ordinary synchronous motor (of the salient-pole, damper-winding type). The circuit employed was a six-phase circuit with six thyratrons, it being preferable to operate a synchronous motor polyphase, instead of single-phase. The grids were excited by an induction phase-shifter of the polyphase type, consisting of a slip-ring induction motor (1/2 hp.), with the rotor turned by a handwheel and worm drive, and insulating transformers for the rotor output. *This phase-shifter was supplied directly from the terminals of the synchronous motor*, so that the inverter was permanently *locked in step* with the motor, and would automatically follow any speed changes. Fundamentally, the phase-shifter determines the *power factor* of the inverter, while the d-c. field of the motor enables adjustment of the a-c. voltage. The a-c. current is nearly proportional to the d-c. current, so that voltage, current, power factor, *and hence power* delivered to the synchronous motor may be adjusted, and if this power exceeds the requirements of the motor, the motor will speed up and vice versa. Hence the speed *and frequency* may be varied by the phase-shifter. The d-c. current and voltage are related by the volt-ampere characteristic of the d-c. supply circuit, so that the frequency *vs.* phase-shifter characteristic will be different, for example, in a constant-potential d-c. circuit than in a circuit of more nearly constant-current characteristics. In fact, the effect of the phase-shifter is often almost opposite for the two types of circuits.

The synchronous motor took load up to the maximum rating of the tubes, and *showed no tendency to hunt or to fall out of step*, even when the shaft load was suddenly changed. An a-c. load, single-phase or polyphase, may be supplied from the terminals of the synchronous motor, and in this case, if the shaft of the motor is unloaded, the motor may be called, as usual, a synchronous condenser, since the current leads, unless a highly capacitative load is applied in parallel.

Concerning the definition, "parallel-type inverter," some confusion arises. In polyphase work, a "series-type rectifier (or inverter) circuit" sometimes means that the different phases of a polyphase bank of transformers and tubes have their d-c. terminals connected *in series*, to accommodate the higher voltages, with the inference that when the various phases are connected in parallel for lower voltages (as in multiple-anode polyphase railway circuits), the term "parallel-type" should be employed. In fact, the title suggested a polyphase circuit, while Mr. Tompkins described a single-phase circuit, such as might be a single-phase unit of a polyphase system.

A General Theory of Systems of Electric and Magnetic Units

BY VLADIMIR KARAPETOFF*

Fellow, A.I.E.E.

***Synopsis.**—A system of electric and magnetic units may be shown to be characterized by five parameters, namely: a numeric, n, which gives the ratio between the density of electric displacement used in that system and the so-called theoretical density; a numeric, p, which gives the corresponding ratio for magnetic flux densities; a physical conversion factor, k, which converts a given volume of current into the corresponding magnetomotive force; the absolute permittivity, κ; and the absolute permeability, μ. On the basis of these five parameters, the principal fundamental equations of electricity, magnetism, and electromagnetic waves are written in what the author calls the general system of units, without assigning definite values to these parameters. He also shows that the five parameters must satisfy the equation* $vk = \sqrt{np/\kappa\mu}$, *where v is the velocity of propagation of electromagnetic waves in that particular medium to which κ and μ refer; otherwise the five parameters may be chosen arbitrarily.*

By giving these parameters specific values, seven different systems of units are derived, namely, the electrostatic, the electromagnetic, the practical, the Gauss system, the Heaviside-Lorentz system, one which the author calls the compromise system, and the ampere-ohm system introduced by him some twenty years ago.

The characteristics, the advantages, and the disadvantages of each system are briefly discussed, and it is shown how to deduce a new system of units from the general system, to conform to certain desired specifications.

At the end of the article a discussion is given on the physical dimensions of various electric and magnetic units. The author states that four fundamental units are necessary for a system, so that if a certain length, mass and time interval are taken as three fundamental units, a fourth electric or magnetic unit must be added, for example, the permittivity or the permeability. In the ampere-ohm system two mechanical fundamental units are used, the centimeter and the second, and two electrical units, the ampere and the ohm.

* * * * *

IT IS generally conceded that the present situation in regard to the electric and magnetic units is far from being satisfactory, for the following reasons:

a. Two or three systems of units are in general use (c.g.s. and practical), at least two more are employed by some prominent writers (the Gauss system and the Heaviside-Lorentz system), and new ones are being proposed from time to time.

b. The absolute magnitudes of some units fixed by international agreement, or in general use otherwise, are considered as being too small or too large by some investigators, who urge the adoption of smaller or larger units.

c. There is an appreciable disparity between the "absolute" c.g.s. units and the corresponding "international" units.

d. The physical dimensions of the electric and magnetic quantities are believed by some scientists to be different in different systems of units. Some physicists even believe it legitimate to assign an arbitrary physical dimension to a quantity, for example, to assume the absolute permeability of any medium to be a numeric; see Section IX below.

It is not the purpose of the present investigation to extol one of the existing systems of units in preference to the others, or to propose a new system of units. The author merely intends to show that all the existing systems are special cases of a General System of Units and may be obtained from it by assigning definite numerical values to certain parameters. Moreover, new systems of units may be produced out of this General System, to satisfy certain desired conditions. In this manner, the argument about systems of units is reduced to that of the possible choice of most convenient values of parameters in the general system, and the burden of proof is shifted from a general discussion to that of particular convenience in a group of applications. It is hoped in this way to contribute to a satisfactory adjustment of the difficulty (a) above. Moreover, the relationship among the corresponding units in the different systems, which is one of the main stumbling blocks in actual use, follows directly from the manner in which a particular system of units is related to the General System. The question of the physical dimensions of a quantity is settled by reference to the dimensions of that quantity in the General System of Units. The same physical quantity can hardly be expected to have two different physical dimensions in two special systems derived from the same General System. This question is discussed more fully in Section IX below.

The difficulty (b) above has existed and always will exist in many branches of quantitative natural sciences. It is clear that atomic dimensions and interstellar distances cannot be conveniently measured with the same yardstick, any more than the current of a photoelectric cell and the current through a large metallurgical steel furnace. This difficulty is minimized by using a multiplying factor of ten to a convenient integral power. From the point of view of applications it is immaterial whether the millimeter or the meter is used as a primary unit, or whether a millisecond or a megasecond is chosen as the primary unit of time. The same applies to units of magnetic flux, power, etc. The use of the factor ten to an integral power is not only inevitable, but quite convenient in applications.

The difficulty (c) is in the process of being rectified.

---

*Professor of Electrical Engineering, Cornell University, Ithaca, New York.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

Due to a better experimental technic, it ought to be possible before long to reach a new agreement in regard to the slight corrections to the present international values of the ampere and the ohm, so as to bring them more closely in accord with the corresponding multiples of the c.g.s. values.

* * * * *

In order to derive a consistent set of equations of the principal phenomena in electricity and magnetism, we shall abandon the historical point of view and look upon these phenomena as being known to us without any chronological precedence of discovery. Besides, we shall introduce factors of proportionality in a general form, without ascribing to them definite values, such as 1, 4π, c, etc. In this manner, it will be possible to derive some general relationships first and obtain various existing systems of units as special cases later. The kinship of the systems and their salient features will then become apparent.

I. ELECTROSTATIC RELATIONSHIPS

We begin with the recognized fact that an electrostatic field may be established, say in vacuum, by suitably placing electric charges here and there. We agree to measure the intensity of such a field at a point by the mechanical force exerted by the field upon a small concentrated electric charge, say an electron, placed at that point. Thus, one of our starting points is the equation

$$f_e = Gq \tag{1}$$

where f_e is the mechanical force, G the field intensity (voltage gradient) and q the probe charge.* The subscript e stands for "electrostatic." The force f_e is to be measured in any chosen mechanical units which are to go with the electric and magnetic units. G thus becomes defined as the mechanical force per unit charge. Of course, equation (1), by itself, is not sufficient to define both unknowns, q and G, and it is to be looked upon only as one of a set of simultaneous equations which together are sufficient for defining the principal electric and magnetic quantities; see Appendix. Consequently, it is immaterial whether equation (1) or equation (8) is introduced first, the latter being the familiar Coulomb's law of inverse squares. The fundamental quantities are not defined "step-by-step," but all the fundamental phenomena and the equations which express them are considered on a par in the set of final formulas.

For purposes of definition of units equation (1) may be said to contain two unknown quantities in the same sense as the familiar relationship in elementary mechanics

$$\text{force} = \text{mass} \times \text{acceleration}.$$

Here the acceleration may be assumed to be known from a more elementary subject, namely kinematics; however, the unit mass must be also defined before this equation, alone, can be used for the definition of unit mechanical force.

All the equations which are to be used in the deduction of the quantities in the proposed General System of Units must be based either on immediate results of some measurements, or on conclusions derived from observed facts and from an assumed mechanism at work. Some physicists may be inclined to consider equation (8) to be more fundamental than equation (1), yet the latter is being constantly verified in various measurements on electronic velocities, accelerations, and impacts. With the advance in the physical and chemical theories, certain ultra-microscopic mechanisms have to be postulated that lead to relationships which can be measured in bulk only. Thus, the Boltzmann-Maxwell distribution of molecular velocities in a gas, the mean free path, etc., can be verified only indirectly. From this point of view, equation (1) is also an experimental relationship and not an *a priori* assumption.

As another fundamental phenomenon, let us consider the dielectric flux and its density due to an electric charge, say Q, concentrated upon a sphere of very small radius ζ. It is an experimental fact that the total dielectric flux due to such a charge is the same through any imaginary concentric sphere or other surface which encloses the charge. In the language of theoretical physics, the divergence of an electrostatic flux in a space devoid of electric charges is equal to zero. The simplest assumption to make is that this flux is numerically equal to the charge which causes it, since experiment shows the two to be proportional to each other. We shall call the value of the flux expressed in such units as to be numerically equal to the corresponding charge the "theoretical" value. In a given system of units it may be necessary to multiply this value by a numerical factor in order to obtain the actual flux in that system of units. At a distance $R > \zeta$ from the center of our charge, the area of the imaginary concentric sphere is $4\,\pi R^2$, so that the "theoretical" density of displacement is

$$D_t = Q/(4\,\pi R^2) \tag{2}$$

where the subscript t stands for "theoretical." In a chosen system of units another value of density of displacement, say D, proportional to D_t, may be used, so that, generally speaking,

$$D = nD_t \tag{3}$$

where n is a numeric. Thus, for example, in the c.g.s. electrostatic system, as used by Maxwell, $n = 4\,\pi$.

The physical properties of a dielectric in which an electric displacement takes place are expressed by its so-called absolute permittivity, which we shall denote by κ. Except under very special laboratory conditions, there is no saturation in dielectrics, and experiment shows that G is proportional to D. We thus have, as a definition of κ,

$$D = nD_t = \kappa G \tag{4}$$

As a special case, for vacuum,

$$D_v = nD_{vt} = \kappa_v G \tag{5}$$

---

*For complete Notation see page 726.

It is convenient to express the absolute permittivity of a medium by indicating the number of times by which it is greater than that of vacuum, in the same system of units. We may thus write

$$\kappa = K\kappa_v \qquad (6)$$

where κ is the absolute permittivity of the dielectric in question, κ_v is that of vacuum, and K is known as the dielectric constant or specific inductive capacity. It is also proper to call K the relative permittivity of the dielectric. K is a numeric, whereas κ and κ_v are physical quantities which have, or may have, physical dimensions. Substituting for D_t its value from equation (2) in equation (4), gives

$$G = nQ/(4\pi\kappa R^2) \qquad (7)$$

Equation (1) therefore becomes

$$f_e = nQq/(4\pi\kappa R^2) \qquad (8)$$

This is the familiar Coulomb's law of inverse squares in an isotropic dielectric whose absolute permittivity is K. Instead of being accepted as a fundamental experimental fact, this law has been deduced here from two other general experimental facts, namely, (a) in a homogeneous isotropic dielectric which is free of charges an electrostatic flux is solenoidal, that is, its divergence is zero; and (b) an electrostatic stress at a point and the corresponding density of displacement are proportional to each other. For the purposes of this paper it is immaterial whether equation (8) is assumed as fundamental and the conclusion that the flux is solenoidal deduced from it, or *vice versa*. In either case, experimental facts are strictly adhered to, and the reader need not have an uneasy feeling that physical truths are being derived from mental ideas.

As a digression, it may be of interest to mention that the attraction or repulsion between two point charges in a three-dimensional space being inversely as the square of the distance, may be thought of as a consequence of the fact that the areas of two concentric spheres are as the squares of their radii. In other words, the density (and consequently the intensity) of the electric field due to one of the charges varies inversely as the square of the distance, because the flux has no divergence. Similarly, in a two-dimensional space with solenoidal fields, the mechanical force between two point charges may be expected to vary as the first power of the distance, because circles take the place of the spheres. This is confirmed by the fact that the mechanical force between two parallel infinitely long filamental charges, per unit length, varies inversely as the distance between them. If it may be assumed that the electric flux in a Euclidean space of Z dimensions is also solenoidal, the mechanical force between two concentrated charges should be taken as inversely proportional to $(Z-1)$st power of the distance, because of the geometric properties of the space.

Let Φ_e be an electrostatic flux expressed in some system of units and let Φ_{et} be the same flux in "theoretical" units, defined above by the condition that

$$\Phi_{et} = Q \qquad (8a)$$

From equation (3) we then obtain

$$\Phi_e = nQ \qquad (8b)$$

The latter expression is Gauss' theorem in the General System of Units.

II. Magnetic Relationships

On the assumption that free magnetic poles actually exist, a set of formulas may be written down by analogy with those developed for electric charges above. True, such an assumption is out of harmony with the modern ideas of molecular structure, and a theory of magnetism can be built up without bringing in the idea of free poles at all. However, the proposed General System of Units must include the c.g.s. electromagnetic system as a special case, and since the latter has the Coulomb law of mechanical force between free magnetic poles for its starting point, it is advisable to include the concept of magnetic pole in our General System of Units. The formulas containing such poles explicitly need not be used in applications.

By analogy with G, we define the magnetic (or magnetizing) intensity, H, at a point in a magnetic field as the mechanical force exerted at that point upon a unit magnetic pole. This gives the relationship.

$$f_m = Hm \qquad (9)$$

analogous to equation (1). Here m is the strength of a probe magnetic pole, and the subscript m signifies that a magnetic phenomenon is meant. By analogy with equation (2) we have

$$B_t = M/(4\pi R^2) \qquad (10)$$

where M is a concentrated magnetic pole and B_t is the so-called "theoretical" density of magnetic flux which M produces at a distance R from its center. Equation (5) becomes

$$B = pB_t = \mu H \qquad (11)$$

Here B is the magnetic flux density used in a chosen system of units, p is a numerical coefficient which gives the ratio between this flux density and the above-defined theoretical flux density; μ is the absolute permeability of the medium. Of course, μ may have definite physical dimensions, although at present they cannot be expressed through those of length, time, and mass alone. By analogy with the absolute and relative permittivity, we introduce the notation

$$\mu = \mu_r\mu_v \qquad (12)$$

Here μ is the absolute permeability of a medium, μ_r its relative permeability, and μ_v is the absolute permeability of vacuum. The quantity μ_r is a numeric. By analogy with equations (7) and (8), we may write

$$H = pM/(4\pi\mu R^2) \qquad (13)$$

$$f_m = pMm/(4\pi\mu R^2) \qquad (14)$$

The latter equation is Coulomb's law of inverse squares for magnetic poles. By analogy with equations (8a) and (8b), Gauss' law for magnetic poles becomes:

$$\Phi_{mt} = M \qquad (14a)$$

$$\Phi_m = pM \qquad (14b)$$

III. THE TWO LAWS OF CIRCUITATION

When electricity is in motion along certain paths, magnetic lines of force are formed in such a manner as to be linked with the paths of the current. This general experimental fact may be quantitatively expressed by the following relationship:

$$k[(1/n)\,(\partial\Phi_e/\partial t) + IN] = \oint H\,ds\cos(H, ds) \qquad \textbf{(15)}$$

In this equation the right-hand side represents the line integral of magnetic intensity H along a closed path; this line integral is known as the magnetomotive force. The relationship is similar to that between an electric intensity, G, and its line integral known as the electromotive force. On the left-hand side of the equation we have the total volume of current threading the closed curve chosen on the right-hand side. In the most general case, in an imperfect dielectric, the current is partly that of displacement of electric charges and partly a true conduction current. Φ_e is an electrostatic flux due to moving charges; dividing it by n converts it into the theoretical flux or actual charge, according to equations (**8a**) and (**8b**). The rate of change of this charge with the time gives the displacement current. The term NI represents the volume of the conduction current, where I is the current itself and N the number of turns through which it is flowing. The coefficient k characterizes a chosen system of units and converts a current into the corresponding magnetomotive force. In a perfect dielectric the IN term is equal to zero. In a metal conductor the term containing Φ_e may be omitted. The factor k may be assumed to have definite physical dimensions, because it converts an electric quantity into something different. What the dimensions of k are, we do not know.

In a special case of an infinitely long straight conductor carrying current I, the lines of magnetic force are concentric circles. At a distance R from the center line of the conductor, the length of a line of force is $2\,\pi R$, so that, with Φ_e = const. and $N = 1$, equation (**15**) becomes

$$kI = 2\,\pi RH \qquad \textbf{(16)}$$

which is the general form of the law of Biot and Savart.

An equation similar to equation (**15**) may be written for a change of a magnetic flux with the time (Faraday's law of induction). In the General System of Units this law becomes:

$$-\,(k/p)\,(\partial\Phi_m/\partial t) = \oint G\,ds\cos(G, ds) \qquad \textbf{(17)}$$

The right-hand side is the line integral of electric intensity G over a closed curve, in other words, the electromotive force induced along this curve. The magnetic flux threading through this curve is Φ_m, and its rate of change with the time is experimentally known to be proportional to this e.m.f. The factor p converts the flux expressed in a particular system of units into the "theoretical" number of lines of force, equation (**14b**). The factor k characterizes the system of units used and converts a time rate of change of a flux into an e.m.f. At first sight, no reason is evident why the factor k should be the same in equations (**15**) and (**17**), but this is proved below from energy considerations. In equation (**17**) the term corresponding to NI is omitted, because no magnetic current is known to exist which corresponds to an electric conduction current.

As a special case of equation (**17**), consider a uniformly wound torus ring connected to a source of direct current through a switch. The ring is also provided with a concentric secondary winding consisting of N turns and connected to a ballistic galvanometer. Let the primary circuit be initially open and then suddenly connected to a source of direct current. The absolute magnitude of the secondary induced voltage at an instant t will be $(k/p)\,N(\partial\Phi_m/\partial t)$. This voltage is used up in the resistance drop ir and the inductive drop $L\,di/dt$ of the secondary circuit. Thus, for an interval of time dt we have:

$$(k/p)N\,d\Phi_m = ir\,dt + L\,di \qquad \textbf{(18)}$$

Integrating this expression with respect to time, from the instant at which the primary switch is closed until the flux has practically reached its final value and the secondary current vanished, we obtain:

$$(k/p)\,N\Phi_m = rQ \qquad \textbf{(19)}$$

where Q is the total electric discharge through the ballistic galvanometer (integral of idt) in units of electric charge. The term with L vanishes because $i = 0$ at both limits. Equation (**19**) is more convenient in some applications than equation (**17**), and moreover it connects a magnetic flux with an electric charge, which is of importance in studying units.

IV. STORED ENERGY

The energy stored in a charged condenser may be looked upon either as concentrated on the metal electrodes, or as distributed in the dielectric in the form of electrostatic stresses and displacements. Of course, numerically the two expressions for the stored energy are identical, but the second form permits us to introduce the useful concept of density of stored energy, or energy stored per unit volume of the dielectric. Consider in particular a parallel-plate condenser which is being gradually charged from zero to a charge Q. At some intermediate instant, t, let the instantaneous accumulated charge be q and let dq be the charge added during the interval dt. If the stress in the dielectric is G and the distance between the plates a, the work done in bringing this additional charge will be:

$$dW_e = aG\,dq \qquad \textbf{(20)}$$

The true electrostatic flux density is q/A, where A is the area of either plate, so that, in accordance with equation (**4**),

$$G = (q/A)\,(n/\kappa) \qquad \textbf{(21)}$$

Consequently

$$dW_e = anq\,dq/A\kappa) \qquad \textbf{(22)}$$

or, after integration,

$$W_e = anQ^2/(2\,A\kappa) \tag{23}$$

Dividing both sides of this equation by the volume of the dielectric, aA, gives the density of electrostatic energy

$$W_e' = W_e/(aA) = n(Q/A)^2/(2\,\kappa) = nD_i^2/2\,\kappa \tag{24}$$

From this expression we may immediately write

$$W_e' = nD_i^2/(2\,\kappa) = D^2/(2\,n\kappa) = GD_i/2 = GD/(2\,n) = \kappa G^2/(2\,n) \tag{25}$$

Since the magnetic concepts introduced above have been assumed to be formally analogous to those in electrostatics, we may also write

$$W_m' = pB_i^2/(2\,\mu) = B^2/(2\,p\mu) = HB_i/2 = HB/(2\,p) = \mu H^2/(2\,p) \tag{26}$$

V. PROOF THAT THE FACTOR k IN EQUATIONS (15) AND (17) IS THE SAME

Let us calculate the magnetic energy stored in a torus ring excited with direct current. This energy is equal to the electric energy put into the exciting winding during the process of bringing the flux from zero to its final value. According to equation (17), that portion of the applied voltage which at an intermediate instant t balances the counter e.m.f. of the flux, is:

$$e = (k/p)N\,d\Phi_m/dt \tag{27}$$

Multiplying both sides of this equation by $i\,dt$, where i is the instantaneous value of the exciting current, we obtain

$$eidt = (k/p)Ni\,d\Phi_m \tag{28}$$

The left-hand side of this equation gives the energy contributed from the source of electric power. Consequently, the right-hand side represents the increase in the stored magnetic energy. In order to be able to integrate the right-hand side, between zero and the final value of the flux, we shall express both i and Φ_m through the magnetic intensity H. If the cross-section of the flux is A and the flux density B, we have

$$\Phi_m = BA = \mu HA \tag{29}$$

Let the average length of the lines of force within the torus ring be a; then the total magnetomotive force is aH, and according to equation (15) it is equal to $k'iN$. Here the value of k is temporarily denoted by k', and it is required to prove that it is equal to the value of k in equation (17). Thus,

$$Ni = aH/k' \tag{30}$$

Substituting the values from equations (29) and (30) in equation (28) and integrating between the limits $H = 0$ and $H = H$, we obtain for the stored magnetic energy the expression

$$W_m = (k/k')\mu H^2 \,.\, aA/(2\,p) \tag{31}$$

so that the density of energy is

$$W_m' = (k/k')\mu H^2/(2\,p) \tag{32}$$

Comparing this expression with formula (26), we see that $k' = k$.

VI. RELATIONSHIP BETWEEN THE PARAMETERS OF A SYSTEM AND THE VELOCITY OF LIGHT

So far the five parameters n, p, k, κ, and μ of a system of units have been assumed to be entirely arbitrary and independent of one another. It will now be shown that they must satisfy the experimental fact that the velocity of propagation of electromagnetic waves in a medium characterized by κ and μ is equal to the velocity of light in that medium. Consider a plane electromagnetic wave propagated in a perfect dielectric in the direction of the X-axis, the electric and magnetic intensities being parallel to the Y and Z-axes respectively. For any point in the medium, equation (15) becomes (references 12, 14, 16)

$$(k/n)\partial D/\partial t = \partial H/\partial x \tag{33}$$

while equation (17) gives

$$(k/p)\partial B/\partial t = \partial G/\partial x \tag{34}$$

In these equations, D may be replaced by κG and B by μH, so that only the functions G and H remain. H can be eliminated by taking a partial derivative of equation (33) with respect to t and a partial derivative of equation (34) with respect to x. The result of elimination is the following well-known partial differential equation of wave propagation for G as a function of t and x:

$$v^2\partial^2 G/\partial x^2 = \partial^2 G/\partial t^2 \tag{35}$$

An identical equation may be deduced for H. In these equations the new parameter, v, is determined by the relationship

$$vk = \sqrt{np/(\kappa\mu)} \tag{36}$$

The parameter v may be shown to be the velocity of propagation of electromagnetic waves in the particular medium characterized by the absolute permittivity κ and absolute permeability μ. For the vacuum the well-known magnitude of the velocity of propagation of light or of electromagnetic waves is usually denoted by c, so that we have

$$ck = \sqrt{np/(\kappa_v\mu_v)} \tag{37}$$

This is the relationship which must be satisfied by the parameters n, p, k, κ_v and μ_v of a system of units. In other respects the parameters may have arbitrary values. Thus, we are free to choose four out of five parameters, and the fifth must satisfy equation (37).

It must be understood that a choice of numerical values of four out of the five parameters merely singles out a group of systems of units, and not a specific system of units, because one is still at liberty to select desired "non-electrical" fundamental units, such as those of length, time and force (or mass). Therefore, it is not meant that in equation (37) the velocity of light should necessarily be measured in centimeters per second or in some such universally used units. Having chosen arbitrarily the values of four electromagnetic parameters, some units of length and time must also be chosen independently, and the velocity c

expressed in these units before equation (**37**) may be applied. Thus, the velocity of light is placed on no special or preferred basis.

The use of equation (**37**) will become more clear in the applications in the next section.

VII. TABULATION OF THE PARAMETERS FOR SOME EXISTING SYSTEMS OF UNITS

In Table I the values of the five parameters which characterize a system of units are shown for the principal systems in use or proposed. The "eruption of 4 π's," using Heaviside's expression (reference 5), is apparent in the first four systems, and has been one of the reasons for the introduction of the later systems indicated in columns 5 and 7. The table may be conveniently studied in connection with the list of the principal formulas given in the Appendix. These formulas are explained in the text above and the numbering is the same.

It is not the purpose of this paper to advocate or to defend any particular system of units, but only to show how all the existing systems and an infinite number of new ones can be derived by giving different values to the five parameters which satisfy equation (**37**) and also choosing desired units of length, time and, say, mass. Looking first at the values of n and p in Table I it will be seen that the existing systems may be divided into those in which the value of these parameters is 4 π, and those in which this value is equal to unity. The first group of systems may be called "classical," the second "rational," or "rationalized." The term rational has been often used by the defenders of the latter systems, and is employed here in that specific sense, without in any way implying that the 4 π systems are "irrational." The author is almost tempted to suggest the adjective "pi-less" in place of "rational."

The advantage claimed for a rational system ($n = p = 1$) is that the flux density in such a system (both electrostatic and magnetic) becomes equal to the theoretical flux density; equations (**3**) and (**11**). This means that the total electrostatic flux due to a charge is both numerically and dimensionally equal to that charge; equation (**8b**). The same applies to a magnetic pole and the flux issuing from it; equation (**14b**). Thus, Gauss' theorem simply becomes $\Phi_e = Q$ and $\Phi_m = M$.

As another advantage of a rationalized system it is pointed out that in dealing with geometric shapes of fields, the factor π appears with cylinders and spheres, as is to be expected, and does not appear with rectangular shapes. The opposite is the case with the classical systems. For example, in the c.g.s. electrostatic system of units the capacitance of a sphere in vacuum is equal to its radius R, and the capacitance of a plane-parallel condenser is $\kappa A/4\pi a$. On the other hand, in the Heaviside-Lorentz system these values are $4\pi R$ and $\kappa A/a$ respectively. Again, in the electromagnetic system, the density of stored magnetic energy in a non-magnetic body is $B^2/8\pi$, whereas in the ampere-ohm system it is $B^2/2\mu_v$. The fact that μ_v in the latter system contains 4π is not supposed to weaken the argument. The user of this system of units simply knows that μ for ordinary non-magnetic bodies is equal to 1.257×10^{-8}, this being an experimental physical constant, and the presence of the factor 4π need not be explained theoretically, as is the case with the classical systems.

Of course, an expert who has been using the classical systems for a number of years finally learns to place the factor 4π where it belongs, but undoubtedly this factor is a stumbling block to a student and a young investigator. In a rational system, the factor 4π is retained in the expression for Coulomb's law of inverse squares, equations (**8**) and (**14**), for the reason that 4π enters in the formula for the surface of a sphere in equations (**2**) and (**10**).

Substituting the values of the five parameters of the electrostatic system in equation (**37**), we obtain

$$4\pi c = \sqrt{(4\pi)^2 c^2}$$

which is an identity. In the same manner it may be shown that the parameters of the other six systems given in the table satisfy equation (**37**).

It will also be seen that no particular units of length and time need be specified so long as it is only desired to express the electromagnetic parameters in terms of c

TABLE I—VALUES OF THE PARAMETERS IN SOME TYPICAL SYSTEMS OF UNITS

System number	1	2	3	4	5	6	7
Parameter	Electrostatic	Electromagnetic	Practical	Gauss	Heaviside-Lorentz	Compromise	Ampere-ohm
k	4π	4π	4π	$4\pi/c$	$1/c$	$4\pi/c$	1
n	4π	4π	4π	4π	1	1	1
p	4π	4π	4π	4π	1	1	1
κ_v	1	$1/c^2$	$1/c^2$ (not used)	1	1	$1/(4\pi)$	$10^9/(4\pi c^2)$
μ_v	$1/c^2$	1	1	1	1	$1/(4\pi)$	$4\pi/10^9$
Fundamental units	cm gram sec κ	cm gram sec μ	10^9 cm 10^{-11} gr sec μ	cm gram sec κ, μ	cm gram sec κ, μ	cm gram sec κ, μ	cm. ampere ohm sec.

algebraically. Thus, one may say that there is an infinite number of electrostatic systems of units, all characterized by the values $k = n = p = 4\pi$ and $\kappa_v = 1$. For all such systems $\mu_v = 1/c^2$. With the centimeter and the second independently chosen as fundamental non-electrical units, $c = 3 \times 10^{10}$, and therefore $\mu_v = (1/9) \times 10^{-20}$. With the kilometer and the microsecond as such units, $c = 0.3$ and $\mu_v = 1/0.09$. In some investigations it is convenient to choose $c = 1$; in the corresponding electrostatic system $\mu_v = 1$.

A similar reasoning applies to all the columns in Table I, each column (with the exception of the last) standing for an infinite number of systems of units all characterized by the same values of four out of five parameters, the fifth being expressed in terms of the velocity of light, c. The last horizontal row in Table I indicates which particular units of length, time, and mass have been chosen in the system of each type actually in use. These non-electrical units may be changed at will, still retaining the general electric and magnetic characteristics of the system.

The symbol κ written at the bottom of column 1 means that historically the electrostatic system of units was built on the assumption of a definite magnitude for the absolute permittivity of the vacuum, more particularly $\kappa_v = 1$. The symbol μ at the bottom of the second and third columns signifies that these systems were built on the assumption $\mu_v = 1$. In the systems shown in the columns 4 and 5 it was simultaneously assumed that $\kappa_v = 1$ and $\mu_v = 1$. In column 6 it is postulated that $\kappa_v = \mu_v = 1/(4\pi)$, for reasons of symmetry explained later. In the ampere-ohm system no attempt is made to fix the values of κ_v and μ_v, this particular system having been devised to take advantage of the existing values of the ohm and the ampere (irrespective of their historical origin) and of the simplicity of having $k = n = p = 1$.

It is left for the reader to substitute the values of the parameters given in Table I in the various formulas given in the Appendix and to satisfy himself that familiar expressions are obtained as a result. It may be of interest here to mention briefly the reasons for which the systems shown in the table have been proposed and used.

In the beginning, say late in the eighteenth century, no connection was known between electric charges and magnetic poles; therefore, there was no necessity for expressing the magnetic and the electrostatic quantities in one and the same system of units. Since the concept of "action at a distance" was prevalent among the French savants of that time, a deduction of formula (**8**) in a manner similar to that given in the text above was not possible. Two charges or two magnetic poles were found by experiment to exert upon each other a force inversely as the square of the distance, so that the natural assumption was (especially for the mathematical school of physicists) to write $f_e = Qq/R^2$ and $f_m = Mm/R^2$, for air or vacuum. The added assumption was that in the electrostatic system κ_v was equal to unity and in the electromagnetic system μ_v was equal to unity. Later the values of relative permittivity and permeability were added as a factor in the denominators of these formulas, to account for newer experimental results. These two formulas thus served as a basis for the c.g.s. electrostatic and electromagnetic systems of units respectively. In our notation, the omission of the factor 4π in the denominators of equations (**8**) and (**14**) is equivalent to the assumption $n = p = 4\pi$; it is in this way that the factor 4π came into the mathematical theory of electricity and magnetism and has kept physicists struggling with various systems of units ever since.

Later, Biot and Savart found experimentally that the magnetic field due to an infinitely long straight current-carrying conductor could be expressed by the formula $H = 2I/R$, and Laplace gave his familiar differential expression for the interaction between a magnetic pole and an element of current, in the form $H = ids \cos \theta/r^2$. This was equivalent to assuming $k = 4\pi$ in equations (**15**) and (**16**), and also meant $k/p = 1$ in equations (**17**) and (**19**), as was later found by Faraday. Of course, those investigators did not think in terms of the General System of Units here described, but their assumptions based on other arguments were equivalent to assigning the values of the parameters indicated in Table I. Having four out of five parameters fixed, the remaining ones (μ_v in the electrostatic system and κ_v in the electromagnetic system) also became determined.

Later it was found that the ratios of the various quantities in the two systems, 1 and 2, were simple functions of the velocity of light, c, although the reason for this did not become clear until after Maxwell had published his electromagnetic theory of light. This relationship between κ_v, μ_v and c is the one given by equation (**37**) which connects the five parameters with the velocity of light. It is because of this relationship that the absolute magnetic permeability of vacuum in the electrostatic system is found to be numerically (although not necessarily dimensionally) equal to $1/c^2$, and the same value comes out for the permittivity of the vacuum in the electromagnetic system.

Consider again equation (**8**), first written in an electrostatic system of units and then in an electromagnetic system, the fundamental units of length, time, and mass being the same in the two systems. Assume equal charges, $q = Q$ and $q' = Q'$, in vacuum; let primed letters refer to the electromagnetic system. Let R be the same in both cases, and let q and q' be physically the same charge, so as to have the same force on the left-hand side. We then have

$$q^2 = c^2(q')^2$$

where the factor c^2 comes in on account of the value of the permittivity in the second system. Thus, the unit of electric charge in an electromagnetic system is c times that in an electrostatic system with the same fundamental non-electrical units. In the particular case of the two c.g.s. systems the ratio equals 3×10^{10}, this being the numerical value of c. By a similar reasoning, the ratio of the units in any two systems in Table I can be readily determined, it being only necessary to write the same formula in the two systems of units.

The so-called practical system of units, with the volt, the ampere, and the ohm as the fundamental units, was originally introduced as a modification of the c.g.s. electromagnetic system, because of inconvenient sizes of the units of potential, current, and resistance in the latter system. The actual assumed ratios are as follows:

one volt = 10^8 c.g.s. electromagnetic units.
one ampere = 10^{-1} c.g.s. electromagnetic units.
one ohm = 10^9 c.g.s. electromagnetic units.

With the magnitudes of any two of these units fixed, the third one is determined by Ohm's law. At the bottom of column 3 in the table, two of the basic non-electrical units of the practical system are given as 10^9 cm. and 10^{-11} gram. While theoretically this would be so if the practical system of units were used as a *pure* system, in reality it is used as a *hybrid* system. Most practising engineers would be surprised were they told that the current density in a generator or transmission line should be measured in amperes per quarter of the earth's meridian squared. In applications, current density and flux density are measured per sq. cm., or per sq. mm., and no one measures magnetizing force in gilberts or ampere-turns per quarter of earth's meridian. Moreover, the practical system of units has not been universally extended to the magnetic quantities; magnetic fluxes are often expressed in maxwells, with the factor 10^{-8} added at proper places. The same is true of many electrostatic computations which are conducted in the c.g.s. system and only the results are converted say into microfarads.

VIII. SOME MORE RECENT SYSTEMS OF UNITS

Since the systems characterized in columns 4 to 7 in Table I are less familiar than the first three systems, it may be of interest to analyze briefly their raison d'être from the point of view of the formulas given in the Appendix.

A glance at column 4 will show that those who prefer the system associated with Gauss' name (refs. 2 and 15) do so because they find it convenient to assume both the absolute permittivity and the absolute permeability of the vacuum to be equal to unity. This, together with the assumption $n = p = 4\pi$, means that in this system electric charges are measured in electrostatic units and magnetic poles or fluxes in electromagnetic units. The other quantities come out in one or the other system of units depending upon the method of their derivation, that is, whether through the parameter n or p. It will be noted that the parameter k has the factor c in it, since c has been omitted from both κ_v and μ_v. This automatically adjusts the equations in which both electrostatic and electromagnetic quantities enter. For example, on the left-hand side of equation (16), when written in the Gaussian system, I is expressed in electrostatic units, being derived from Q, whereas H is in electromagnetic units. Dividing I by c (which enters in k) converts it into electromagnetic units. In equations (17) and (19), dividing Φ_m by c converts it into electrostatic units, to agree with the quantities on the right-hand side of the equations. In other words, the Gaussian system enables one to express a quantity in that system from which it has been fundamentally derived; the factor c is put explicitly in the circuitation equations, thus doing away with converting the quantities before substituting them in these equations.

A system of units in which $n = p$ and $\kappa_v = \mu_v$ may be called a symmetrical system, and the Gaussian system, as well as those shown in columns 5 and 6, are symmetrical systems. One of their advantages is that the fundamental formulas for electrostatic and magnetic relationships become formally identical. Thus, formulas (7) and (13), as well as (8) and (14) have the same factor $n/\kappa = p/\mu$. The same is true of the circuitation equations (15) and (17), provided that $I = 0$, and of the energy equations (25) and (26). This symmetry is considered by some physicists to be quite valuable in teaching and in some investigations.

Heaviside also believed such characteristics of a system of units to be desirable, especially in theoretical investigations of general nature where a formal symmetry of magnetic and electric equations and of the two circuital relationships is important. He objected only to 4π which enters in three parameters in the Gaussian system. What he did was equivalent to changing the values of n and p from 4π to 1 (making the system "rational" in his sense). As a result, 4π also dropped out of k, in accordance with equation (37). An inspection of equation (8) will show that, in effect, Heaviside left f_e and the denominator on the right-hand side unchanged, but omitted the factor $n = 4\pi$ in the numerator. Consequently, the numerical values of q and Q had to become $\sqrt{4\pi}$ times greater, or, which is the same, the unit of charge made smaller in the same proportion. The same reasoning applies to equation (14), so that in the Heaviside system of units all the principal electric and magnetic quantities differ from those in the two c.g.s. systems by factors containing $\sqrt{4\pi}$. Moreover, the quantities themselves are either in electrostatic or in electromagnetic units (*not* c.g.s.), depending upon the method of their derivation, precisely as the Gauss' system, and the factor c is introduced in the value of k. The Heaviside system of units has been used by some prominent writers in Europe and in the United States (refs. 5, 9, 11, 13) because of the simplicity and symmetry of the formulas. In general theoretical deductions, such as the properties of electromagnetic waves, motions of electrons, and the like, the magnitude of the units is of no particular consequence until the final formulas have been reached. In substituting the numerical values, the factor $\sqrt{4\pi}$ has to be properly taken into account. A detailed tabulation of the ratios between the classical and Heavisidian units will be found in reference 11.

To the author's knowledge, the system tabulated in column 6 and called the compromise system has been neither proposed nor used heretofore. It is mentioned here, not because he is in favor of it, but merely to show how easily a new system of units could be devised on the basis of the General System of Units in which the equations in the Appendix are expressed. Assume a hypothetical investigator or teacher who is dissatisfied with the two c.g.s. systems, first because the user constantly has to convert quantities from one to the other, and secondly because of the presence of 4π in the values of n and p, making it necessary to consider carefully whether this factor enters in the numerator or denominator of a particular formula. He is not satisfied with the Gauss system either, because of the same 4π, and he objects to Heaviside's system of units because one has to convert the usual c.g.s. units into his units with the aid of the factor $\sqrt{4\pi}$. So, to accomodate this scientist, we devise a new "rational" system of units, that is, one for which $n = p = 1$. The value of κ_v in equation (8) has to be equal to $1/4\pi$ in order to have the same unit of charge as in the c.g.s. electrostatic system. The same is true of μ_v in equation (**14**). Having the values of the four parameters thus prescribed, equation (37) gives $k = 4\pi/c$.

It may be stated in passing that the occurrence of 4π in the expressions for κ_v and μ_v is not nearly so objectionable from the beginner's point of view as in the parameters n and p. After all, κ_v and μ_v are physical constants, and the user or the student merely needs to know that with the universally accepted values of units of current and resistance these constants come out numerically equal to 0.07958 ($= 1/4\pi$). He need not question the reason for this value any more than he does the numerical value of the conductivity of copper, the electronic charge, or any other physical constant. On the other hand, when a flux is taken to be 4π times the charge which causes it, and when 4π enters everywhere with parallel planes and disappears with cylinders and spheres, much more explanation is necessary. Perhaps a frank admission that 4π should have been used in the initial statement of both Coulomb's laws is the easiest and most honest way out. In Goethe's words, "woe unto you because you are a grandson!" In other words, had Heaviside been born fifty years earlier, before the two c.g.s. systems and their units became firmly established, his views and his system of units would probably have been universally accepted.

The dilemna then is, either to use new fundamental units for current, resistance, etc., as Heaviside did (column 5), or to preserve the present units and accept 4π in the values of κ_v, μ_v, and k, as is done in the compromise system (column 6). Had Heaviside urged his system before the older values of Q and M came into general use, his solution would have been perfect. We simply would have had different values of units of current, e.m.f., etc., than we do at present. A glance at column 5 does not show a single 4π.

The ampere-ohm system (refs. 7 and 8) shown in the last column has been laid out to satisfy the following requirements:

1. The new system of units must be "rational," that is, $n = p = 1$, but for practical purposes it need not be symmetrical, that is, μ_v need not be equal to κ_v, as in the columns 4, 5, and 6.
2. It must be based upon the generally recognized international units, to wit, the ampere, the ohm, and their derivatives, the volt, the farad, the henry, the ampere-turn, etc. However, the historical connection of these units with the corresponding c.g.s. units must nowhere appear explicitly.
3. There should be only one set of units, for both electromagnetic and electrostatic computations, because in modern physics and engineering both kinds of quantities often enter in the same equations.
4. The velocity of light c and the factor 4π must be completely eliminated from the working formulas so that their presence need not be explained theoretically.
5. The question of inconvenient sizes of the fundamental units need never arise, because the prefixes milli, micro, mega, etc., are to be freely used, as well as 10 to suitable integral powers (a hybrid system). For practical uses, a system need not be pure. A hybrid system with milliamperes, megohms, square decimeters, etc., is just as convenient, if not more, than a pure consistent system with inconvenient magnitudes of the units.
6. The values of κ_v and μ_v are to be taken as physical constants, with definite physical dimensions, and need not be simple integers, such as 1 or 2, any more than we expect other physical constants to be simple integers in a chosen system of units.
7. With the ampere, the ohm, and the second as the fundamental units, the joule becomes the natural unit of energy, and therefore one joule per centimeter the fundamental unit of mechanical force; the author has used the name *joulecen* for this unit of force since 1910 (ref. 8).
8. The mechanical force being included under the fundamental units, no unit of mass need be specified. The centimeter and the second are to be taken as the two other non-electrical fundamental units.

In laying out such a system, we assume from the beginning that $n = p = k = 1$, thus rationalizing it completely in so far as the general theory of electricity and magnetism is concerned. The factor π is to appear only in problems involving surfaces or volumes of cylinders and spheres. The ampere-turn becomes the unit of magnetomotive force, and H in equations (**15**) and (**16**) is to be expressed in ampere-turns per centimeter. The right-hand side of equation (**17**) being in volts, and

$k/p = 1$, the unit flux is such a flux which induces one volt per turn when this flux disappears or is built up at a uniform rate exactly within a second. In other words, fluxes are measured in volt-seconds; the name "weber" has also been proposed for such a unit.

To deduce the value of μ_v in the ampere-ohm system theoretically, consider equation (**11**), $B = \mu_v H$, written in this system, and compare it with the same relationship, $B' = H'$, in the c.g.s. electromagnetic system. Since the unit of flux in the ampere-ohm system is 10^8 times that in the other system, we have $B' = 10^8 B$. The magnetizing force, H, in the ampere-ohm system is equal to NI/a, where I is in amperes. In the c.g.s. electromagnetic system, $H' = 4\pi(NI/a)\ 10^{-1}$, because in this system $k = 4\pi$ and the unit of current is equal to ten amperes. Thus, we have

$$10^8 B = (4\pi/10) NI/a \qquad \textbf{(38)}$$

and also

$$B = \mu_v NI/a \qquad \textbf{(39)}$$

Comparing these two expressions, we find that in the ampere-ohm system

$$\mu_v = 4\pi/10^9 \qquad \textbf{(40)}$$

To deduce the value of κ_v in the ampere-ohm system theoretically, use equation (**8**) in application to two equal charges at a distance R, in vacuo. In the ampere-ohm system

$$f_e = Q^2/(4\pi\kappa_v R^2) \qquad \textbf{(41)}$$

whereas in the c.g.s. electrostatic system

$$f_e' = (Q')^2/R^2 \qquad \textbf{(42)}$$

Here f_e is expressed in joulecens and f_e' in dynes. Since a joule is equal to 10^7 ergs, a joulecen is equal to 10^7 dynes; that is, $f_e' = 10^7 f_e$. We first convert Q into c.g.s. electromagnetic units (abcoulombs) by dividing it by 10, and then convert abcoulombs into electrostatic units by using the conversion factor c. Thus, $Q' = cQ/10$. Substituting this value in equation (**42**) and comparing the result with equation (**41**) we get

$$\kappa_v = 10^9/(4\pi c^2) \qquad \textbf{(43)}$$

It will be seen that the values of the five parameters given in column 7 of Table I satisfy equation (**37**). In fact, having determined μ_v, the value of κ_v could have been deduced directly from equation (**37**).

The reader will thus see that with the general equations of electricity and magnetism written in the form given in the Appendix, new systems of units can be multiplied indefinitely, as shown on a few examples above. Each system so far developed satisfies certain "specifications" and may be the best system for a particular purpose or set of problems. It is hardly feasible to speak of the best all-around system of units; at least none has been universally accepted as such so far, despite numerous discussions and arguments. With the General System of Units expounded in this paper, all the systems now in existence, and possibly some of the new ones to be evolved in the future, may be looked upon as specific cases of this system. Therefore, the argument about systems of units becomes localized along a few definite lines, such as the following: (a) Is it desirable to have a "rationalized" system of units; (b) Should the best system be also "symmetrical"; (c) Should any of the existing international electric or magnetic units be made part of it; (d) What are to be the fundamental non-electrical units; (e) Should it be a pure or a hybrid system of units; etc. It will be readily seen that anything like a universal agreement among the physicists and engineers of the various countries on all these points is a remote possibility. A more hopeful initial program may consist in a gradual elimination of the older and less used system of units.

IX. PHYSICAL DIMENSIONS OF QUANTITIES

The broad question of physical dimensions of units is not necessarily connected with the introduction of the General System of Units, and persons holding quite opposite views on dimensional analysis (ref. 21) may find the proposed derivation of various systems of units from a single more general system useful. A brief discussion of physical dimensions is included in the paper, partly for the sake of completeness and partly to bring out a subsequent discussion of conflicting views on the subject of dimensional formulas. The controversy hinges on whether the physical dimensions of a quantity, say mechanical force or inductance, are inherent in that quantity or are a matter of convenience and somewhat arbitrary. The author takes the point of view that for those investigators whose field of activity lies primarily in applied problems, it is both simpler and safer to consider the physical dimensions of a quantity as inherent in its nature (although perhaps unknown to us). With this assumption, the ratio of the magnitudes of the same quantity in two different systems of units can be only a numeric. It would be out of the question to state that the ratio of the units of electric charge in the two c.g.s. systems is equal to the velocity of light; this ratio is an abstract quantity and can only numerically equal the velocity of light. Otherwise it could be claimed that the ratio of a square meter to a square foot is equal to 10.76 gram-seconds!

The opposite point of view is ably defended by some leading physicists skilled in dimensional analysis, and the author can best indicate their general attitude by quoting an esteemed colleague who saw this paper in manuscript form: "Many people seem slow to realize that physical dimensions are purely a matter of convenience, as Bridgman has so ably shown in his little book on Dimensional Analysis. I think Professor Karapetoff becomes almost mystical in this last section of his paper. However, he has plenty of company in the attitude he takes. . . . In several places throughout the paper in speaking of dimensions the author speaks as if dimensions were inherent objective properties amenable to physical investigation. This attitude toward dimensions is similar to the attitude taken in a paper by Professor Kennelly on a related subject published a year or two ago. It will appear to many readers, including the present one, that the assignment of dimensions is altogether arbitrary and subject to no physical investigation; it is suggested, therefore, that a discussion should be included of this matter, proving either that dimensions are inherent and amenable to physical investigation or else that they are purely arbitrary. . . . . As an example, the dimensions of volume may be considered. It is customary to assign the dimension L^3 to volume for the reason that the volume of a cube, for instance, is obtained by raising its side to the third power. It would be equally correct to say that the volume of the cube equals a constant of numerical value unity but having some arbitrary dimension assigned to it multiplied into the cube of the side. In this case we are impelled to make the constant dimensionless by the feeling that the result will be greater simplicity rather than by the knowledge that volume inherently possesses the dimension L^3."

The author grants some strength to this argument and is the first one to welcome a generalization of our customary doctrines in the hands of scientists of the first rank who work upon an extension of the fundamental physical concepts and the underlying philosophy of ideas in physics. He only feels that for the rank and file of the profession it is safer and wiser to adhere to a more limited attitude of inherent physical dimensions. The remarks which follow represent distinctly this point of view, and the author hopes that more advanced and flexible views upon the subject may be contributed to the discussion of this paper.

In our present state of knowledge, it is impossible to express the physical dimensions of electric and magnetic quantities in terms of mechanical units alone, for example, of mass, length, and time. The dimensions of at least one electric or magnetic quantity have to be assumed as fundamental, in addition to the mechanical units. For example, in the electrostatic system of units the numerical value of κ, is put equal to unity, but its physical dimensions should be taken as something fundamental and not reducible to the units of length, mass, and time. This is indicated in the last horizontal row of Table I by stating whether κ or μ is used as the fourth fundamental unit. In the systems 4, 5, and 6, the dimensions of some units are expressed through κ, of others through μ. In the ampere-ohm system the physical dimensions as well as the magnitudes of the ohm and the ampere are considered as fundamental. For this reason, only two mechanical fundamental units are necessary, those of length and time. Energy and force are expressed in terms of electric power, I^2r.

It is also possible to take the physical dimensions of voltage, inductance, electrostatic flux, or any desired electric or magnetic quantity as fundamental, and to express the physical dimensions of the rest of the quantities in its terms. For an engineer and applied physicist it is safer to adhere to the view that in nature the physical dimensions of an electric or magnetic quantity are intrinsic in that quantity and do not depend upon a human system of units or upon a choice of the fundamental units. While outwardly these dimensions may look different in different systems of units, this may be simply due to our ignorance of the intrinsic nature of the phenomena involved. It is therefore safer not to maintain (as is sometimes done) that in the electrostatic system of units absolute permittivity is a numeric, whereas in the electromagnetic system its physical dimensions are those of a velocity to the power of minus two.

From a practical point of view, a more conservative statement is as follows: In the electrostatic system of units the physical dimension of permittivity is a fundamental dimension. Therefore, calling the numerical value of an absolute permittivity (κ) and its physical dimension $[\kappa]$, we have

$$\kappa = (\kappa)\,[\kappa] \tag{44}$$

In the electromagnetic system of units μ is a fundamental unit. From equation (**36**), the dimension of permittivity (assuming for the present k to be a numeric) is

$$[\kappa] = [\mu]^{-1}\,[v]^{-2} \tag{45}$$

Therefore, in this system

$$\kappa = (\kappa)\,[\mu]^{-1}\,[v]^{-2} \tag{46}$$

Intrinsically, however, the physical dimensions indicated in equations (**44**) and (**46**) are identical; their product has the dimensional formula (time/length)^2, to agree with equation (**37**).

In the ampere-ohm system, the dimensions of κ may be deduced from equation (**5**). The flux density has the dimensions of a quantity of electricity divided by an area, or $[\mathrm{D}] = [i][t][A]^{-1}$. The dimensions of the voltage gradient are those of a voltage divided by a length, or $[G] = [I]\,[r]\,[a]^{-1}$. Consequently,

$$[\kappa] = [D][G]^{-1} = [t][r]^{-1}[a]^{-1} \tag{47}$$

The physical dimensions of various quantities in the principal systems of units in use will be found in refs. 4, 11, and 17. For the corresponding tabulation in the ampere-ohm system see refs. 7 and 8. It may also be added that from the point of view maintained by the author the ratio of unit charges in the two c.g.s. systems is only *numerically* equal to the velocity of light in vacuo; the ratio itself can only be a numeric.

The problem of physical dimensions is further complicated by the question of the physical dimensions of the parameter k. In equation (**15**) this parameter changes a current into a magnetomotive force, and in equation (**17**) it converts a rate of change of flux into a voltage. Since the purely physical side of these transformations is still enshrouded in mystery, it may be just as well for the present *provisionally* to consider k to be a numeric. From the physical point of view this may be equivalent to the assumption that there are no transformations in kind, so that a current *is* a magnetomotive force and a change in flux *is* an induced e.m.f.

Nevertheless, it is well to keep in mind the possibility of a later discovery of the intrinsic nature of these circuital relations. For this reason, it seems both wise and considerate towards future generations not only to preserve this parameter, but to grant beforehand the possibility of its having definite physical dimensions. This may forestall for our posterity a difficulty similar to the one we are having with 4π.

The author therefore heartily seconds Dr. W. Jaeger's proposal, (ref. 3, table on page 35) of including the dimensions of k with those of the magnetic quantities. When studying his table the reader should keep in mind that Jaeger's k is different from the one used in this article, being defined by his equations (28) and (29), even though the general purpose of both parameters is the same.

NOTATION

A	cross-section of an electric or magnetic path
a	length, usually of a line of force
B	magnetic flux density
c	velocity of light in vacuum
D	dielectric flux density, or density of displacement
e	as a subscript, means "electrostatic"
f	mechanical force
G	potential gradient, or electric field intensity
H	magnetizing force, or magnetic field intensity
I, i	electric current
k	a parameter which characterizes a system of units with respect to the two laws of circuitation, equations (15) and (17)
K	relative permittivity, or dielectric constant
L	inductance of a circuit
M, m	strength of a magnetic pole
m	as a subscript, means "magnetic"
N	number of turns in a winding
n	a parameter which characterizes a system of units and gives the ratio of the dielectric flux density used in that system to the so-called theoretical flux density; equation (3)
p	a parameter which characterizes a system of units and gives the ratio of the magnetic flux density used in that system to the so-called theoretical flux density; equation (11)
Q, q	magnitude of an electrostatic charge
R	distance measured from the center of a charge or conductor
r	electrical resistance of a circuit
r	as a subscript, means "relative"
s	variable length along a closed curve
t	time
t	as a subscript means "theoretical"
v	velocity of electromagnetic waves in a perfect dielectric
v	as a subscript, means "vacuum"
W	stored electrostatic or magnetic energy
W'	same, per unit volume
x	direction of propagation of a plane electromagnetic wave
κ	absolute permittivity of a dielectric
μ	absolute permeability of a magnetic medium
Φ	electrostatic or magnetic flux
ζ	radius of a small sphere

Appendix

TABULATION OF THE PRINCIPAL FORMULAS IN THE GENERAL SYSTEM OF UNITS

The equation numbers are the same as in the text.

$$f_e = Gq \tag{1}$$

$$D_t = Q/(4\pi R^2) \tag{2}$$

$$D = nD_t \tag{3}$$

$$D = \kappa G \tag{5}$$

$$\kappa = K\kappa_v \tag{6}$$

$$G = nQ/(4\pi\kappa R^2) \tag{7}$$

$$f_e = nQq/(4\pi\kappa R^2) \tag{8}$$

$$\Phi_e = nQ \tag{8b}$$

$$f_m = Hm \tag{9}$$

$$B_t = M/(4\pi R^2) \tag{10}$$

$$B = pB_t = \mu H \tag{11}$$

$$\mu = \mu_r \mu_v \tag{12}$$

$$H = pM/(4\pi\mu R^2) \tag{13}$$

$$f_m = pMm/(4\pi\mu R^2) \tag{14}$$

$$\Phi_m = pM \tag{14b}$$

$$k[(1/n)(\partial\Phi_e/\partial t) + IN] = \oint Hds \cos (H, ds) \tag{15}$$

$$kI = 2\pi RH \tag{16}$$

$$-(k/p)\,(\partial\Phi_m/\partial t) = \oint Gds \cos (G, ds) \tag{17}$$

$$(k/p)N\Phi_m = rQ \tag{19}$$

$$\begin{aligned} W_e' &= nD_t^2/(2\kappa) = D^2/(2n\kappa) = GD_t/2 \\ &= GD/(2n) = (\kappa G^2/(2n) \end{aligned} \tag{25}$$

$$\begin{aligned} W_m' &= pB_t^2/(2\mu) = B^2/(2p\mu) = HB_t/2 \\ &= HB/(2p) = \mu H^2/(2p) \end{aligned} \tag{26}$$

$$(k/n)\,\partial D/\partial t = \partial H/\partial x \tag{33}$$

$$(k/p)\,\partial B/\partial t = \partial G/\partial x \tag{34}$$

$$v^2\partial^2 G/\partial x^2 = \partial^2 G/\partial t^2 \tag{35}$$

$$v^2\partial^2 H/\partial x^2 = \partial^2 H/\partial t^2 \tag{35a}$$

$$vk = \sqrt{np/(\kappa\mu)} \tag{36}$$

$$ck = \sqrt{np/(\kappa_v\mu_v)} \tag{37}$$

Discussion

Lloyd Champlin Eddy: Such statements on the general relations of units as were presented by Mr. Karapetoff may prove to be of ultimate value for more thoroughly understanding universal relations, even of certain forms of life also. Who knows what manifestations of life are not fundamentally electric in nature? Perhaps two physical phenomena most resembling life are radio-activity and magnetism, both electrical phenomena. Both of these phenomena apparently depend on certain relations or numbers of electrons or atoms much as animal life itself appears mainly where carbon is present in more or less definite relations with other elements. The extension of our knowledge of the general relations of units in electrical engineering as well as other fields, therefore, may be of considerable interest also to those interested not only in the fundamental units of science and electrical engineering but in universal relations of physical life.

A Proposal to Abolish the Absolute Electrical Unit Systems

BY ERNST WEBER*

Associate, A.I.E.E.

***Synopsis.**—The specification of a physical quantity must include numerical value and unit. The expression "dimension" is defined as the general unit of a quantity and it is shown that applied mathematics has to deal with physical quantities rather than pure numbers, so that each equation yields a relation between numerics and dimensions. It is possible to reduce all dimensions to a set of a few fundamental dimensions, called a "dimension system." The application of this concept to the various fields of physics is shown, and it is proved that the so-called "absolute" dimension systems in electromagnetism are incorrect from this point of view and lead to inconsistent results. The proposal is made, therefore, to abolish the "absolute" dimension systems in electromagnetism and to introduce two new dimension systems as extensions of the two well-known mechanical systems by adding just one electric fundamental dimension. The new proposal retains all the familiar units but puts them on the sound basis of correct dimension systems, which, it is hoped, eliminates the unfortunate discrepancy in electromagnetism which has caused so much trouble ever since the "absolute" systems were introduced. The adoption of the new proposal, however, requires the cooperation of physical as well as electrical engineering societies, especially with regard to possible international action.*

* * * * *

INTRODUCTION

THE fundamental discovery that the ratio of the "absolute" electrostatic unit to the "absolute" electromagnetic unit of electric charge, predicted as a velocity, was apparently identical with the velocity of light,[1] brought about an unforseen confusion in the field of electrical units. The use of various "absolute" dimension systems, expressing the electric and magnetic quantities by means of the three mechanical fundamental dimensions, influenced the writing style of formulas and caused the introduction of factors in various places where they seemed quite arbitrary. At the same time that A. E. Kennelly delivered a paper on "magnetic reluctance"[2] and caused a long discussion as to the position of the factor 4π, Heaviside in London prepared a paper on "the eruption of the 4π's."[3] Heaviside was apparently the first to notice that the dielectric constant and the permeability of free space ought to be considered as physical quantities, but he made no proposals as to their definite dimensions.

Since then a veritable flood of articles and papers has been published in the important periodicals of the world, concerned either with a new system of electric and magnetic units or dimensions, or with a comprehensive basic system of mechanical units. None of them has succeeded as yet, because of the *attitude of respect toward the classical absolute systems*, which have exerted an unfortunate power of tradition, especially in the field of physics. This paper aims to prove conclusively the incorrectness of these classical dimension systems and to propose *natural systems* which, it is hoped, may finally settle the differences and put the electrical unit systems on a sound basis.

In order to provide the means for a logical proof and to furnish the necessary elements for building up the new systems, the paper deals first with the fundamental conception of the dimension of a physical quantity, in so far as it is necessary for the scope of this paper.

I. Physical Quantities, Their Units and Dimensions

The aim of all physical science is to obtain a description of the inorganic world in terms of mathematics. The scientific type of human mind tends to bring all relations into forms which are more or less mathematical and in doing this is concerned fundamentally with the process of measurement.

A. THE DIMENSION OF A PHYSICAL QUANTITY

The following statements are a brief summary of the fundamental conception of physical quantities in so far as they differ from pure numbers and must form the true basis of all considerations concerning the problem of units and unit systems. In order to emphasize the importance of each statement, the special arrangement in form of letter paragraphs has been chosen.

α. To determine definitely the value of a physical quantity, it is necessary to make *two statements*; one indicating the *unit* which is used in measuring the quantity, and the other giving the *number of units* involved in the result of that measurement. For example, to state "the length of the path is 4" is an incomplete statement because the unit may be *m*, cm., inch, foot, mile, or so on, each of the units being widely different. The theoretical number of possible units, obviously, is infinity.

β. However, all the various units of length form an infinite group of similar quantities, each one being a definite length itself, so that $[l]$ may stand as a symbol for any one unit of length. The statement, "the length of the path is $4 \cdot [l]$ "is still incomplete, but in this case there is at least the indication that a physical quantity is involved and it is therefore necessary to specify a length unit.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

γ. At this point the *dimension* of a quantity is defined by the infinite reservoir of possible units for that quantity. A physical quantity is then generally designated by

$$N \cdot [D], \tag{1}$$

where N is the numeric and $[D]$ is the symbol for the dimension. A special value of that quantity is obtained by specifying the values of N and $[D]$. The conception of a physical quantity as the product of numeric times dimension corresponds to the process of measuring, which essentially consists in *first* fixing $[D]$ as a definite unit (usually with a definite name), and *then* comparing the given quantity with this unit.[4,5]

From this point of view, dimension is as necessary as the numerical value and can not be abstracted from a physical quantity without reducing it to a pure number.* It should be noted that the word dimension is often used with other meanings, as for example: three-dimensional space, four-dimensional world, and so on. This should not be confused with the definition given above.

δ. Comparison of the same quantity, measured with two different units leads to the mathematical relation

$$N_1 \cdot [D]_1 = N_2 \cdot [D]_2,$$

where $[D]_1$ and $[D]_2$ designate definite units. If the following unit relations exist

$$[D]_1 = n_{12} \cdot [D]_2, [D]_2 = n_{21} \cdot [D]_1 \tag{2}$$

then

$$\begin{aligned} N_1 \cdot [D]_1 = N_1 \cdot n_{12} \cdot [D]_2 &= N_2 \cdot [D]_2 \\ &= N_2 \cdot n_{21} \cdot [D]_1 \end{aligned} \tag{3}$$

illustrating the process of changing units. It must be emphasized, however, that the conversion factors n_{12}, n_{21} *must be pure numbers*, in order to make the units comparable at all, *i. e.*, all units of the same quantity must have the same dimension. This statement is identical with that in β or γ and is extremely important in passing on the correctness of unit systems.

B. Applied Mathematics and Physics

Pure mathematics operates with symbols designating numbers and numbers only. It is closely related to geometry in so far as all expressions may be interpreted in terms of coordinates, and their relations producing geometrical forms, such as surfaces, curves or points. The extension of these interpretations to hyper spaces is well known.

Applied mathematics, however, uses the laws and methods deduced by pure mathematics in order to solve the problems arising in physics, chemistry, and the related engineering sciences. All physical relations involve physical quantities, since they can be found or proved only experimentally. The only means for finding quantitative laws is by measuring the various quantities involved. This conclusion is thus identical with the statement at the beginning of the previous chapter and it is obvious now, that before experimental investigations can proceed, it is necessary that the means for measurement, *i. e.*, the units, must be available.

In this paper no attempt is made to give a historical review of the development of measuring quantities and determining units in the various fields of physics. However, a brief introductory review of the fields of physics may be given in order to prepare for the following presentations.

The dominating law of physics is undoubtedly the law of conservation of energy. It is known that energy appears in various forms, but that the total quantity of energy can not be changed. Energy is therefore the *only true fundamental quantity* which ties together all the various fields of physics.

A fundamental scheme for distinguishing between the various fields of physics would appear to be the subdivision according to the different forms of energy. This method would lead to the following classification:

Mechanics. The mechanical energy appears in the two forms—potential energy and kinetic energy.

Heat. In this case there is only the single form energy which may be called heat energy or molecular energy.

Electricity. Here the energy manifests itself as the electric field energy and magnetic field energy.

These three fields of physics are the only ones which have been discovered so far. It is unnecessary at this point to speculate as to the possibility of a common origin of these various forms of energy.

It is obvious from what has been said in (A) that, whatever unit we choose for energy, all such units in the various fields of physics must have the same dimension and can be converted into one another. Since the research work in the various fields was carried on independently it is but natural that different units of energy were chosen. Table I gives a short review of the units most frequently used and the relations existing between them.

TABLE I

Mechanical energy......	1 kg force m	= 9.806 joules	= 9.806×10^7 ergs
Heat energy............	1 cal.	= 10^3 cal	
Electromagnetic energy .	1 wattsec		

Inter-relations

1 kg force m = 2.34 cal = 9.806 wattsec.

II. The Mathematical Forms Used in Physics

Theory in any respect is descriptive. The mathematical type of human mind searches for relations between quantities, progressing in each field toward the fundamental laws upon which the final theory may be built. The laws are expressed in mathematical forms and the whole chain of relations, *the theory*, is then the *mathematical picture* of the respective physical field.

---

*However, the dimension has nothing to do with the "ultimate nature" of physical quantities. See also reference 37, chapter 2.

Only when experiment and theory conform exactly can the theory be said to be satisfactory.

The fundamental mathematical form is the equation. There are but two different types of equations* which occur in theoretical work: the arbitrary definition and the statement of experimental proportionality. Because of the importance of these two kinds of equations they will be considered in some detail in this section.

A. The Arbitrary Definition

Many physical laws can be expressed in simpler form, if use is made of defined quantities rather than measured quantities. Thus, the quotient of two physical quantities, Q_1 and Q_2

$$\frac{Q_1}{Q_2} = \frac{N_1}{N_2} \cdot \left[\frac{D_1}{D_2} \right] = N \cdot [D],$$

results as the product of a numerical value N and a dimension $[D]$, *i. e.*, as a physical quantity itself which may or may not have a true physical meaning. At any rate it can be named and used in physical relations as an arbitrarily defined quantity.

The arbitrary definition can also take the form of differential and integral relations, as for example

$$v = \frac{ds}{dt},$$

the definition of velocity being the differential quotient of path and time. Even differentials are parts of the physical quantity, although infinitely small. In general, mathematical operations on physical quantities again give physical quantities.

It is this fact which justifies the comparison of the dimensions on the two sides of any physical relation, or more exactly, any relation in applied mathematics, and such a comparison is a direct consequence of dealing with physical quantities rather than with pure numbers. Thus, each equation can be split up into a relation of numerics, and a relation of dimensions or units depending on whether or not definite units are specified.

B. The Statement of Experimental Proportionality

Our knowledge of natural phenomena is due primarily to the research of experimental physics, and the mathematical expression of these experimental investigations is always the statement of a proportionality. For example, the relation

$$F = k \cdot \frac{Q_1 Q_2}{r^2}$$

represents the experimental relation describing the force existing between two masses, two electric charges, or two magnetic poles, if their centers are separated a distance $r \cdot [l]$. In all three cases the proportionality factor k serves to express the proper quantitative dependence. This means, however, that k has *two* functions, namely, to balance the numerical values as well as the units used for the known physical quantities on both sides of the equation. It is obvious, therefore, that generally k itself appears as a *physical quantity*.

In many cases this fact is recognized by giving a characteristic name to the proportionality constant. In some important cases attempts were made to specify quite arbitrarily the meaning of the proportionality factor, thereby emphasizing the least important quantity in the whole equation. It will be shown that this procedure leads to inconsistent as well as incorrect results.

III. On Dimension Systems and Unit Systems

A. Definitions of Dimension Systems and Unit Systems

In order properly to express its value, a physical quantity must be definitely specified as to its numerical value and unit. However, it would be too confusing to use as many unit names as there are physical quantities. As pointed out above, there are many relations between the various quantities, either as definitions or as experimental proportionalities, which permit a reduction in the number of unit names.

Since each relation between quantities can be split up (see chapter II A) into one relation of numerics and another one of dimensions (as general units), it is possible to combine all known relations of dimensions. In setting up these relations, all proportionality factors must be taken as physical quantities. If there are m *independent* relations known, and $(m + p)$ dimensions involved, it indicates that m dimensions can be expressed in general by any p "fundamental" dimensions chosen arbitrarily.

This set of p "fundamental" dimensions is then called a *dimension system*. From the theory of numbers therefore, it is known that one generally has a choice of $\binom{m+p}{p}$ possible dimension systems. Thus, if $p = 3$, $m = 3$, then one has $\binom{6}{3} = 20$ different possibilities. A necessary condition, however, is that *each* independent relation involves at least $(p + 1)$ dimensions. If this is not the case, then the number of possible dimension systems is less, so that $\binom{m+p}{p}$ indicates the *upper* limit.

Furthermore, in order to arrive at some method of properly expressing physical quantities it is necessary to choose a unit for each of the p fundamental dimensions. Each set of p units so obtained is a "*fundamen-*

---

*E. Bennett[6] distinguishes 4 types of relations; however, for the purpose of this paper it is but necessary to distinguish according to the mathematical types.

tal unit system." Any unit of the $(m + p)$ quantities can then be expressed in terms of the p fundamental units.

Since each fundamental dimension yields an infinity of possible units, there result "infinity to the p, raised to the $\binom{m+p}{p}$ power," possible fundamental unit systems. This vast array of possibilities must emphasize the desirability of international agreement before too much use is made thereof.

Any dimension system chosen in the described manner, is consistent, as well as correct and never leads to ambiguity with respect to the expression of physical quantities.

B. The Dimension Systems in Mechanics

No attempt is made to give a complete history of the mechanical units. The investigations of this chapter only serve to develop a thorough basis for the derivations of the following ones, and present selected points of interest.

It follows from Appendix A that there are at least $\binom{6}{3} = 20$ possible dimension systems. Since space and time are admittedly the fundamental perceptions for investigating physical phenomena, let $[l]$ and $[t]$ be two of the three possible dimensions. The third dimension could be chosen from $[k]$, $[m]$, $[f]$, $[W]$, thereby restricting the number of possibilities to four. There is no dimension system known, which uses the proportionality constant $[k]$ as a fundamental dimension, but the use of $[W]$ as the third fundamental dimension has been proposed by W. Ostwald[7] without much success. If, then, $[f]$ is taken as the third fundamental dimension, the system becomes the so-called gravitational system, in which the fundamental dimensions are $[l]$, $[t]$, $[f]$. Because of the fact that this system is used to a large extent in engineering, it will be referred to in this paper as the *technical dimension system.* On the other hand, if $[m]$ is chosen for the new dimension there results the so-called dynamical system whose dimensions are $[l]$, $[t]$, $[m]$. Because of the frequent use of this system in physics it will be called the *physical dimension system.* In the latter system the dimension of force becomes

$$[f] = [m] \cdot [l]\,[t]^{-2}. \tag{5}$$

These two dimension systems of mechanics are consistent because they are composed of the required three fundamental dimensions which can be used to specify all the other quantities.[27]

Table II shows, for convenience, the dimensions of various mechanical quantities in both dimension systems, if use is made of the relations given in Appendix A.

The conversion from one system into the other is easily made if the unit systems are specified within the dimension systems. Consider, for example, the same amount of work measured in both dimension systems. In the technical dimension system the equation could be written in the form

$$W = a \cdot ([f]\,[l])_u,$$

where a is the numerical value, and the symbol $(\ \ )_u$ designates the unit. In the physical dimension system the work could be given by

$$W = b \cdot ([m]\,[l]^2\,[t]^{-2})_u,$$

where b is now another numerical value and $(\ \ )_u$ the other unit. Since the same amount of work is involved, equating these two quantities gives the unit relation

$$1\,([f]\,[l])_u = \frac{b}{a}\,([m]\,[l]^2\,[t]^{-2})_u.$$

As emphasized above, units have the same dimensions as the quantities themselves. Equating the dimensions on both sides there results

$$[f] = [m]\,[l]\,[t]^{-2},$$

a dimension relation which is also given in Table II. *No new dimensional relations are ever obtained by measuring quantities in various dimension-systems as long as such systems are consistent.*

It follows from chapter III A that there are "infinity cubed" unit systems possible in each dimension system. In spite of this fact, however, when the two systems were introduced, exactly the same unit names were chosen in both systems. This startling coincidence is perhaps comprehensible, but it is the cause of much confusion in attempting to distinguish the *kg*, *g*, etc., as a unit of force in the one system and as a unit of mass in the other. It has been proposed to call the technical system unit, *kg*-force, and for the sake of clarity this designation will be used here. (See Table I.)

C. The Dimension Systems in Heat

It is surprising to note that in the field of heat a single dimension system has been developed and no confusion whatsoever exists as to its fundamental dimensions. There are, however, many inconveniences as to the units; these difficulties may be settled internationally when scientific minds grow international.

TABLE II

Symbol	Quantity	Technical system	Physical system
	Fundamental dimensions	$[f],[l],[t]$	$[m],[l],[t]$
m	Mass	$[f][l]^{-1}[t]^2$	$[m]$
f	Force	$[f]$	$[m][l][t]^{-2}$
k	Gravitation constant	$[f]^{-1}[l]^4[t]^{-4}$	$[m]^{-1}[l]^3[t]^{-2}$
W	Work, energy	$[f][l]$	$[m][l]^2[t]^{-2}$
P	Power	$[f][l][t]^{-1}$	$[m][l]^2[t]^{-3}$

As may be seen from Appendix B the two fundamental laws in heat involve 6 dimensions, thus requiring 4 fundamental dimensions for a dimension system.[3] Again we assume the two basic perceptions of space and time to be natural fundamental dimensions, and since temperature had been measured long before a theory of heat existed, it is justifiable to take the temperature as a third fundamental dimension $[\theta]$. The fourth dimension can be chosen from

$$[k], [R], [m], [f], [W],$$

if use is made of the definitions in Appendix B whereby $[W]$ can be replaced by either $[m]$ or $[f]$.

Of all these possibilities, the only important system is the one involving $[m]$ and it may be referred to as the "thermophysical" dimension system, since it is based upon the mechanical-physical system. No use has been made of the system involving $[f]$ which might similarly be called the "thermotechnical" dimension system. As mentioned above, the system using $[W]$ had been proposed by Ostwald[7] without success.

The proportionately constant R of Boyle-Charles's law is known as the universal gas constant and its dimension can be read from the law in Appendix B as[9]

$$[R] = [l]^2 \cdot [t]^{-2} \cdot [\theta]. \qquad (6)$$

In concluding this chapter it may be emphasized that, thus far, none of the proportionality factors has been mistreated or taken as fundamental dimensions.

TABLE III—COMPLETE ELECTRICAL DIMENSION SYSTEMS

		Additional fundamental dimension			
		$[Q]$	$[I]$	$[k_e]$	$[k_m]$
	Dimension systems	$[m],[l],[t],[Q]$	$[m],[l],[t],[I]$	$[m],[l],[t],[k_e]$	$[m],[l],[t],[k_m]$
Quantity	Symbol				
Electric charge	Q	$[Q]$	$[I][t]$	$[m]^{1/2}[l]^{3/2}[t]^{-1}[k_e]^{-1/2}$	$[m]^{1/2}[l]^{1/2}[k_m]^{-1/2}$
Current	I	$[Q][t]^{-1}$	$[I]$	$[m]^{1/2}[l]^{3/2}[t]^{-2}[k_e]^{-1/2}$	$[m]^{1/2}[l]^{1/2}[t]^{-1}[k_m]^{-1/2}$
	k_e	$[m][l]^3[t]^{-2}[Q]^{-2}$	$[m][l]^3[t]^{-4}[I]^{-2}$	$[k_e]$	$[l]^2[t]^{-2}[k_m]$
	k_m	$[m][l][Q]^{-2}$	$[m][l]\,[t]^{-2}[I]^{-2}$	$[l]^{-2}[t]^2[k_e]$	$[k_m]$
Electric field strength	E	$[m][l]\,[t]^{-2}[Q]^{-1}$	$[m][l]\,[t]^{-3}[I]^{-1}$	$[m]^{1/2}[l]^{-1/2}[t]^{-1}[k_e]^{-1/2}$	$[m]^{1/2}[l]^{1/2}\,[t]^{-2}[k_m]^{1/2}$
Magnetic field strength	B	$[m][t]^{-1}[Q]^{-1}$	$[m][t]^{-2}[I]^{-1}$	$[m]^{1/2}[l]^{-3/2}[k_e]^{1/2}$	$[m]^{1/2}[l]^{-1/2}[t]^{-1}[k_m]^{1/2}$

IV. The So-Called Absolute Electric and Magnetic Dimension Systems

Confusion seems to have reigned unconfined in the dimension systems of electricity and magnetism, even to the present day. It is the purpose of this section to apply the fundamental principles deduced above to an analysis of these absolute dimension systems.

A. The Electromagnetic Dimension Systems

As indicated in Appendix C, the three independent laws of electromagnetics give relations between seven dimensions, so that four, and not less than four, fundamental dimensions compose an electromagnetic dimension system. Again, the basic perceptions of length and time would seem to justify the choice of $[l]$ and $[t]$ as fundamental dimensions. Since Coulomb's and Ampere's laws are closely related to mechanics, the choice of a mechanical dimension as a third one suggests itself. Inasmuch as both of these laws involve only the force $[f]$, the two definitions given in Appendix C can be used to express $[f]$ in terms of either $[m]$ or $[W]$, so that the third fundamental dimension can be chosen from $[m]$, $[f]$, $[W]$, as in the mechanics. The first two possibilities are the only ones of practical importance as seen from chapter III B.

The fourth fundamental dimension in electromagnetics can then be chosen from

$$[Q], [I], [k_e], [k_m].$$

The last two quantities are the proportionality constants of Coulomb's and Ampere's laws and as such, have no special physical significance. However, even though such a specification of this dimension system is entirely natural and quite convincing, it has been customary to specify as fundamental dimensions[12] those of the proportionality factors k_e and k_m, so that the electric charge and current appear as derived dimensions. This entirely arbitrary procedure is hardly justifiable on the grounds of a logical development of dimensions.

As previously mentioned, each of the four quantities, Q, I, k_e, k_m, can be taken as the new fundamental dimension. The four dimension systems thus obtained are shown in Table III, where the first two columns give the dimensions with integer exponents, and the last two columns have exponents of fractional orders. This again makes it preferable to choose either $[Q]$ or $[I]$ as fundamental dimensions instead of $[k_e]$ or $[k_m]$.*

It is possible to convert from the one electrical system into the other if the units are fixed. Since there are four different systems, four relations for the dimensions of the units are obtainable, as for example, in the case of current:

$$[Q][t]^{-1} = [I] = [m]^{1/2}[l]^{3/2}[t]^{-2}[k_e]^{-1/2} = [m]^{1/2}[l]^{1/2}[t]^{-1}[k_m]^{-1/2}$$

which fits perfectly into the respective columns of Table III. There is not the least ambiguity as to the fundamental dimensions; *i. e.*, the *unit relations are unique*. This is also the reason for calling these systems complete dimension systems, and as such, they cannot have less than four fundamental dimensions.

It may appear possible to obtain a complete set of four fundamental dimensions by choosing *two electrical fundamental dimensions* in addition to length and time. Such an "electrical" set of dimensions has been used by several authors in which current, resistance, length and time are the four fundamental dimensions.[13,14] In this case it becomes necessary (see Appendix C) to introduce the mass as a derived electrical dimension, and so one would "electrify" the mechanical system. From the point of view of international agreement between physicists and engineers, however, such an arrangement would appear to be quite unsatisfactory and undesirable.

---

*In the field of electrical engineering, E. Bennett[8] used a complete practical system, as given in the third column.

B. The "Absolute" Systems and the System of Gauss

The mechanical system of dimensions composed of the three fundamental dimensions, $[m]$, $[l]$, $[t]$, was often called the "absolute system" and it was thought possible to reduce all the dimension systems in the various fields of physics to the same absolute system. This was shown to be impossible in the case of heat, and from the discussion above (see Table III) it ought to be impossible in the case of electromagnetism. However, the first experimental law (Appendix C) presents an almost irresistible temptation to be made the basis of an absolute system. It was thought possible to assign any dimension whatsoever to the proportionality factor and consequently the choice was so made that $[k_e] = 1$; *i. e.*, k_e *degenerated* into a pure number. The third column in Table III gives then the absolute dimensions of the electromagnetic quantities if $[k_e] = 1$. For convenience the result is shown again in the first column of Table IV. Since Coulomb's law occurs in electrostatics, the dimension system has been called the *absolute electrostatic dimension system.*

Another absolute dimension system was specified on the basis of the fundamental law of magnetism, or steady currents. By choosing $[k_m] = 1$ the proportionality factor became a pure number (similar to k_e in the electrostatic system) and Ampere's law (Appendix C) could then be used for determining the absolute dimension of the current. The resulting dimensions may be found in the last column of Table III, introducing $[k_m] = 1$ and is given for convenience in the second column of Table IV. The dimension system based upon this arbitrary choice of k_m is called *absolute electromagnetic dimension system.*

Although each of the above dimension systems is quite arbitrary, it is apparent that they are unsymmetrical, in spite of the fact that the two proportionality factors have the same respective position and are supposed to play the same role. A comparison of the last two columns in Table III will show that the ratio of the dimensions for any quantity in both systems is given by

$$\frac{[k_e]}{[k_m]} = [l]^2\,[t]^{-2}, \tag{7}$$

which is evidently the dimension of the square of velocity.

In order to obtain a symmetrical system, Gauss introduced a new proportionality factor defined by the equation

$$k_m' = k_m \cdot v^2, \tag{8}$$

where v denotes a quantity having the dimension $[l]/[t]$. Because of this substitution the factors k_e and k_m' have then the same dimensions. By specifying $[k_e] = [k_m]' = 1$, *i. e.*, defining both constants as pure numbers, the remarkable result is obtained that all the electric quantities, including the current, are in the electrostatic dimension system, and the magnetic quantities are in the electromagnetic system, as shown in the last column of Table IV.

C. Objections to the Absolute Electrical Dimension Systems

In introducing *arbitrary statements about the proportionality factors* k_e and k_m, *absolute systems have been obtained but the dimensional relations are incorrect.* The proof of this statement can be presented by summing up the more important objections to the various attempts at reducing the number of required fundamental dimensions to less than four.

α. The dimension of the proportionality factors k_e *or* k_m *can not be chosen arbitrarily.* It has been shown in Appendix C that there are three independent relations between mechanical and electrical quantities, involving, however, four new electrical dimensions which must be determined. This means, as explained above, that it is necessary to introduce a fundamental electrical dimension. Defining k_e or k_m as pure numbers, however, means exactly the same as defining the gravitation constant k, in law 2 of Appendix A, as a pure number. On the basis of this supposition, then, the three laws in mechanics would involve only 5 dimensions and there would be only two fundamental dimensions. This means, in other words, that mass, force and energy could be expressed in powers of $[l]$ and $[t]$ alone.

TABLE IV

Quantity	Symbol	Absolute dimension systems Electrostatic $[k_e] = 1$	 Electromagnetic $[k_m] = 1$	 Gauss $[k_e] = [k_m'] = 1$
Electric charge	Q	$[m]^{1/2}[l]^{3/2}[t]^{-1}$	$[m]^{1/2}[l]^{1/2}$	$[Q]_e$
Current	I	$[m]^{1/2}[l]^{3/2}[t]^{-2}$	$[m]^{1/2}[l]^{1/2}\,[t]^{-1}$	$[I]_e$
	k_e	1	$[l]^2[t]^{-2}$	1
	k_m	$[l]^{-2}[t]^2$	1	$[k_m]_e$
Electric field strength	E	$[m]^{1/2}[l]^{-1/2}[t]^{-1}$	$[m]^{1/2}[l]^{3/2}\,[t]^{-2}$	$[E]_e$
Magnetic field strength	B	$[m]^{1/2}[l]^{-3/2}$	$[m]^{1/2}[l]^{-1/2}[t]^{-1}$	$[B]_m$

However, it would not be necessary to stop there, since other arbitrary statements could be made so that the number of dimensions could be further decreased. There is no logical reason for such a procedure and it never can be justified. The theory of dimensions and dimension systems as developed in these previous chapters give, so it is hoped, a definite guide for obtaining proper dimension-relations.

β. *The arbitrary designation of k_e and k_m as pure numbers actually converts the absolute electrical systems into the mechanical dimension system.* Hence, absolute electric, as well as absolute magnetic dimension systems, are in fact parts of the mechanical system. Consequently, since all quantities are measured in the same system, unit relations of the type $1m = 100cm$ ought to hold. However, in both systems *the dimensions are different.** There is thus an *obvious contradiction* which can not be reconciled. It would be similar to a situation, for example, in which velocity had different dimensions if measured in the physical or in the technical mechanical dimension systems. This would be immediately recognized as being incorrect, so that the same conclusion should be drawn in the case of the absolute electrical systems.

γ. *The absolute electrical dimension systems as parts of the mechanical dimension system lead to strange relations.* Since all the absolute electromagnetic systems are based upon the same three fundamental dimensions of mechanics, all electric and magnetic quantities appear as mechanical quantities of the same type. As in the case of the two mechanical dimension systems (chapter IIIB), and as in the case of the complete electrical systems (chapter IVA), the dimensions in the absolute systems may be compared. If these dimension systems are perfect, no new dimensional relations should be obtained.

However, equating the dimensions of Q, I, E, and B, as given in Table IV, gives the strange result

$$[l] \cdot [t]^{-1} = 1,$$

and equating the dimensions of k_e and k_m there results $[l]^2\,[t]^{-2} = 1$. Or, in other words, it ought to be possible to express length by time or vice versa. Needless to say again, the arbitrary statements of k_e and k_m as pure numbers are quite incorrect.

As may be seen from Table IV, even Gauss' System does not succeed in obtaining a mechanical system in electromagnetics. Since the electric quantities are measured in the electrostatic system and the magnetic quantities in the electromagnetic system, exactly the same objections can be made.

δ. *The ratio of the electrostatic to the electromagnetic unit of charge is not equal to the velocity of light.* It has been explained in almost every textbook† that the ratios of electrostatic to electromagnetic units involve a fundamental quantity—the velocity of light, approximately equal to $c = 3.10^{10}\ \dfrac{\text{cm}}{\text{sec}}$. It is known that within the mechanical system, the multiplication of two physical quantities changes the dimension and in general the physical meaning. It is, therefore, a surprising statement that in the absolute electric systems the same electric quantities have units which differ in their *dimensions by a velocity* or some power thereof.

However, introducing the absolute electrostatic unit of charge as defined by Coulomb's law with $k_e = 1$ and $f_e = 1$ dyne, $r = 1$ cm, it follows that

$$1\,([m]^{1/2}\,[l]^{3/2}\,[t]^{-1})_e = 1g^{1/2}\ \text{cm}^{3/2}\ \text{sec}^{-1},$$

which is a very small unit. For practical purposes, the *coulomb* has been introduced so as to give

$$\begin{aligned} 1 \text{ electrostatic unit of charge} &= 1g^{1/2}\ \text{cm}^{3/2}\ \text{sec}^{-1} \\ &= \frac{1}{3.10^{9}} \text{ coulomb.} \end{aligned} \tag{9}$$

On the other hand, the absolute electromagnetic unit of current follows from Ampere's law with $k_m = 1$ and $f_m = 1$ dyne, $r = 1$ cm, $l = 2$ cm, as

$$1\,([m]^{1/2}\,[l]^{1/2}\,[t]^{-1})_m = 1g^{1/2}\ \text{cm}^{1/2}\ \text{sec}^{-1}.$$

The practical unit is defined as the *ampere*, so that

$$1g^{1/2}\ \text{cm}^{1/2}\ \text{sec}^{-1} = 10 \text{ ampere,} \tag{10}$$

and converting to the electromagnetic unit of charge by means of the relation $1cb = 1a \cdot \text{sec}$, there results

$$\begin{aligned} 1 \text{ electromagnetic unit of charge} &= 1g^{1/2}\ \text{cm}^{1/2} \\ &= 10 \text{ coulomb.} \end{aligned} \tag{11}$$

Hence, the ratio of (21) to (23) becomes

$$\frac{1 \text{ electrostatic unit of charge}}{1 \text{ electromagnetic unit of charge}} = \frac{\text{cm}}{\text{sec}} = \frac{1}{3.10^{10}}. \tag{12}$$

and this surprising result shows that the ratio of the units of electric charge gives *the unit of velocity;* but *the ratio of the numerical values of electric charge* gives the *reciprocal of the numerical value of this velocity.*

The last two terms of equation (12) may be written as[18]

$$3.10^{10}\ \frac{\text{cm}}{\text{sec}} = 1. \tag{13}$$

This rather unusual result is a direct consequence of using absolute unit systems. These contradictions have been sanctioned by physics since their introduction and almost no protest has been raised against such relations.

(ϵ) *The form of Faraday's induction law.* In Appendix C, Faraday's induction law is given as a dependent relation and the proportionality factor β which was arbitrarily introduced, turns out to be a pure numeric, if use is made of the general dimension relations given by the 3 independent laws. This indicates that the factor $1/c$ which is necessary in Gauss' dimension system in order to balance both sides of the induction law, has that position only because of the incorrect dimension of either B or E. Again, the inconsistency shows up quite clearly and brings to light the various ingenious ways of correcting equations in order to maintain artificial dimension systems.

---

*The different dimensions always caused difficulties. See references 17, 18, 37.

†As illustrations, some of the most recent valuable textbooks on physics and electrical engineering may be named. See bibliography references 19, 30, 21, 22, 23, 24.

D. CONCLUSIONS AS TO THE ABSOLUTE ELECTRICAL DIMENSION SYSTEMS

All attempts to reduce the required four fundamental dimensions of electromagnetism to the three fundamental dimensions of mechanics by arbitrary statements as to the proportionality factors have failed. Moreover, the consequences of such statements are not in agreement with the normal laws of mathematics as shown in chapter IIIA. The results, therefore, lead to the following conclusion:

The absolute electrostatic, electromagnetic and Gauss' dimension systems in the field of electromagnetics are incorrect and have to be abandoned finally and completely. Reference can *no longer* be made to *c.g.s. systems or to "absolute units" of any quantity in electromagnetics,* since the proper electrical dimension system must have four fundamental dimensions. The notation, *c.g.s. system, occurs only in mechanics* and *has to be restricted to this field of physics,* where it represents just one possible system of units within the "physical" dimension system.

If this denial of the possibility of c.g.s. systems in electromagnetics is granted—and the above proof justifies this conclusion—it must follow at once that the proportionality factors k_e and k_m can not be considered as pure numbers. Their dimensions and numerical values follow from the special type of the dimension system which shall be adopted, if possible, internationally. If k_e and k_m are physical quantities then the *dielectric constant* (permittivity) and the *magnetic constant* (permeability) of free space (being linearly depending on k_e and k_m) are physical quantities. As such they must have numerical value and dimension, similar to the *gravitation constant* k, and the gas constant R, and must be considered to be *of the same universal importance.*

Due to the fundamental importance of the subject and because of the fact that even the most recent textbooks of physics and engineering are using these absolute electrical systems,* international authority in physics and engineering will be required to banish the absolute systems and to introduce a dimension system appropriate to the field of electromagnetism. The various committees could consider the specification of units and unit names only after the absolute systems have been abandoned and a proper dimension system introduced.

There has been much discussion as to the "rationalization" of units; *i. e.*, shifting the factor 4π, involved in Maxwell's field equations, into more natural positions. However, it is meaningless to talk of "rationalized absolute" or "unrationalized absolute" units when the very existence of such absolute units is unjustifiable.

V. On Proper Dimension Systems in Electromagnetism

The fact that the absolute system has been proven to be incorrect makes it necessary to propose a proper dimension system in electromagnetics—one which presents at least some promise of being considered internationally. A selection has to be made between the four complete dimension systems given in chapter IVA, since these systems are directly deduced from the fundamental laws of electromagnetics. However, before making a definite proposal, it will be feasible to consider the so-called practical unit system.

A. THE SO-CALLED PRACTICAL UNIT SYSTEM

The "absolute electrostatic" unit of charge and the "absolute electromagnetic" unit of current (see chapter IVB) were the basis of two unit systems, the c.g.s. electrostatic and the c.g.s. electromagnetic unit systems. Later, both unit systems were found to be quite inconvenient and for practical purposes other units were introduced and defined quite arbitrarily, as shown by the following examples.

1 coulomb $= 3.10^9$ c.g.s. electrostatic units of charge
$= 10^{-1}$ c.g.s. electromagnetic units of charge
1 farad $= 9.10^{11}$ c.g.s. electrostatic units of capacitance
$= 10^{-9}$ c.g.s. electromagnetic units of capacitance
1 henry $= \frac{1}{9} \cdot 10^{-11}$ c.g.s. electrostatic units of inductance
$= 10^9$ c.g.s. electromagnetic units of inductance

Only a few relations are given here for a special purpose, and even these few show a surprising variety of numerical factors.

The practical units are but definitions of units without regard to their dimensions. And, indeed, it would be difficult to state dimensions for these practical units. Take for example, the charge. As shown in equations (**9**) and (**11**) the *coulomb* is related to both dimension systems with the numerical factors given above. Equating (**9**) and (**11**), since the *coulomb* has to be the same unit in both cases, gives

$$3.10^9\, g^{1/2}\, \mathrm{cm}^{3/2}\, \mathrm{sec}^{-1} = 1 \text{ coulomb} = \frac{1}{10}\, g^{1/2}\, \mathrm{cm}^{1/2}. \quad (\mathbf{14})$$

The question naturally arises as to which dimension may now be chosen for *coulomb*. Furthermore, equation (**13**) may be read again if the extreme left-hand and the extreme right-hand terms are considered. Similar contradictions can be obtained for the dimensions of each practical unit.*

---

*See as examples, references 19, 20, 22, 23, 24.

Another strange relation can be obtained for the dimensions of *farad* and *henry*. The following dimension relations can be taken from any conversion table of the absolute electric and absolute magnetic dimension systems:

[c.g.s. electrostatic unit of capacitance] = cm,
[c.g.s. electromagnetic unit of inductance] = cm.

Using the above numerical factors it is permissible to write

$$1\text{ cm} = \frac{1}{9}\cdot 10^{-11}\text{ farads} = 10^{-9}\text{ henrys} \qquad (15)$$

so that it should be possible to express *farads* in terms of *henrys* and vice versa—another proof of the inconsistency of the absolute dimension systems.

In many cases the absolute c.g.s. units were designated as abcoulomb, abohm,[26,27,36] or the abbreviation e.s. volt, and e.m. volt were used for the c.g.s. unit of voltage in the electrostatic and electromagnetic dimension systems.[6] Again, the "practical" unit of magnetic flux was called the pra-maxwell,[28] but an extension of this method would have resulted in complications. All these attempts were quite unsatisfactory but serve as an indication of the many difficulties which were caused by the simple statements that k_e and k_m were to be considered as pure numbers.

The *conclusion stated in chapter IVD* has to be supplemented, therefore, by the condition *that the practical units be completely separated from the absolute systems* and that the conceptions of the dimensions of the practical unit systems be clarified. It is a unique fact that *here is a unit system in daily use and well known* even to nonexperts, but *without the background of a proper dimension system.* In no other field of physics is there such a well-built unit system with such distinguished unit names as in electromagnetics, and yet there is no fundamental basis to justify this system.

Although the practical unit system is complete as to the unit names, it has not been customary until recently to use it as a complete system in the case of Maxwell's field equations. A mixture of the absolute electrostatic, absolute electromagnetic and practical units has been used most frequently, especially in the literature of electrical engineering. Accordingly, Maxwell's field equations are amply supplied with numerical factors in the technical literature.[29] This was the cause of an attempt to choose the practical units ampere, ohm, centimeter and second as a basis for a separate and independent set of electrical units.[13,14] However, the above four units are not a unit *system* and consequently, they are not at all a dimension system as frequently assumed. (See chapter IVA).

This proposal resulted as a reaction against the mixture of absolute systems and as such, took the extreme position of separating the field of electromagnetics completely from mechanics. These attempts have the invaluable merit of having caused a spirited discussion for over twenty years, without, however, achieving a definite result.

B. REQUIREMENTS OF NEW PROPER DIMENSION SYSTEMS

Thus far it has been explained and proved that all existing dimension systems are quite unsatisfactory, the classical systems themselves being incorrect. Greatest care has to be taken in proposing new dimension systems, since such systems should be satisfactory for international consideration.

The *main points in preparing new dimension systems*, according to the results indicated in this paper, can be enumerated as follows: *First,* a single fundamental electrical dimension has to be combined with the three mechanical fundamental dimensions in order to obtain a proper dimension system. There is no possibility of transposition of a purely mechanical dimension system into electromagnetics. *Second,* the expressions of *absolute* units, *absolute* dimensions and *absolute* systems have to be entirely suppressed. *Third,* it is necessary to adhere to the trend in electrical engineering of using the so-called practical *unit* system, but with due regard to a proper and adequate *dimension* system. *Fourth,* the independently defined absolute units have to be introduced into a physical dimension system. These physical units must be related to the so-called practical units by numerical factors. The velocity of light as an important multiplier must disappear finally and completely. *Fifth,* it should be possible to write Maxwell's field equations in such a general way that, by introducing the different unit systems, all the various schemes for writing the equations are obtained. In all cases only numerical conversion factors are involved—the factor 3.10^{10} is in no case to be considered as a velocity. *Sixth,* the dielectric constant and the permeability of free space are not to be taken as numerics, but rather as physical quantities with dimensions derived from the dimension system specified.*

At first glance it would seem almost impossible to find a solution containing all these requirements, especially since no comprehensive solution has been suggested throughout the last forty years of active discussion. However, a satisfactory solution of the problem is possible and the following section contains proposals for such "natural dimension systems."

Before submitting a plan of solution of the problem, it will be convenient for future use to indicate the fundamental equations of the electromagnetic field in homogeneous media.

---

*Tables of such comparative types may even be found in the literature. See reference 25.

*O. Heaviside[3] emphasized this point of view, but did not assign definite dimensions.

$$f_e = k_e \frac{Q_1 Q_2}{r^2} \qquad f_m = k_m \frac{I_1 I_2}{r} l \tag{16}$$

$$k_e = \frac{1}{4\pi} \cdot \frac{1}{\Delta} \qquad k_m = \frac{1}{2\pi} \cdot \Pi \tag{17}$$

$$\Delta = \Delta_0 \cdot \epsilon \qquad \Pi = \Pi_0 \cdot \mu \tag{18}$$

$$\bar{\mathbf{D}} = \Delta \cdot \bar{\mathbf{E}} \qquad \bar{\mathbf{E}} = \rho \bar{\mathbf{G}} \qquad \bar{\mathbf{B}} = \rho \cdot \bar{\mathbf{H}} \tag{19}$$

$$\psi = \iint D_n d\sigma; \quad I = \iint G_n d\sigma; \quad \phi = \iint B_n d\sigma \tag{20}$$

$$W_e = \frac{1}{2} \iiint \bar{\mathbf{E}} \bar{\mathbf{D}} d\tau; P_R = \iiint \bar{\mathbf{G}} \bar{\mathbf{E}} d\tau; W_m = \frac{1}{2} \iiint \bar{\mathbf{H}} \bar{\mathbf{B}} d\tau \tag{21}$$

$$= \frac{1}{2} CV^2 \qquad = RI^2 \qquad = \frac{1}{2} LI^2 \tag{22}$$

$$\text{curl } \bar{\mathbf{H}} = \bar{\mathbf{G}} + \frac{\partial \bar{\mathbf{D}}}{\partial t} \tag{23}$$

$$\text{curl } \bar{\mathbf{E}} = - \frac{\partial \bar{\mathbf{B}}}{\partial t} \tag{24}$$

These forms hold in *any case* where the *same unit system* is used throughout. If units of different systems are employed on both sides of any equation, numerical factors enter the relations, and it will be shown later that these numerical factors are the same as those found in the various forms of equations used for decades. The above *given forms* may be called *rationalized*; but it will be seen later, that the factor 4π can be shifted around simply by choosing the respective combination of units of the various systems in order to obtain all the familiar forms. The factor 4π and the problem of rationalization is not an essential problem for correct expression of the equations; but it is essential that the velocity of light no longer appears in the fundamental laws.

It should be emphasized at this point that the proposals made in the following section are in no sense to be considered as the ultimate or final solution of the problem; but that any other complete analysis must follow this same line of thought. This first discussion then, will confine itself to the fundamental requirements—no final proposal being made as to the notation and symbols to be adopted.

C. Proposal as to Natural Dimension Systems

In all the attempts to settle the confusion of the various unit systems, one fact seems to have been consistently disregarded; namely, that there *already are two mechanical systems* in general use, a technical and a physical one (see chapter IIIB) with their respective fundamental dimensions [*f*], [*l*], [*t*] and [*m*], [*l*], [*t*]. It is but natural to ask—why not supplement both systems by a fundamental electrical dimension and call them respectively, the *electrotechnical and electrophysical dimension systems?* As has been shown in chapter IIIB, both mechanical dimension systems are perfect. If, therefore, an electrical dimension is added, it is to be expected that perfect electrical dimension systems will be obtained (see chapter IVA). This is the substance of the following proposal, for which the dimensional relations and units are given in Tables V and VI.

The *new fundamental electrical dimension* is taken to be the *electric charge*. As previously pointed out in chaper IVA, there are many advantages in specifying the electric charge as a fundamental dimension. In addition to the *natural unit* existing in the electron, the electrotechnical unit *coulomb* is fixed internationally and can be realized electrochemically quite readily. The basis of the electrophysical definition of unit charge is Priestley's law (**16**). By taking the numerical value of k_e for free space equal to unity (but still having a dimension assigned to it), a unit of charge is defined as such a charge, acting on an equal charge at a distance of 1 *centimeter* with a force of one *dyne*. This unit is here called the *priestley* according to the true discoverer of the law[10] and is the fundamental unit.

The dimensions of the true electrical quantities in the third group of the tables are the same in both systems and are expressed in [*l*], [*t*], [*Q*], only. In addition, the dimensions of all other mechanical-electrical quantities (related to the mechanical forces in the electromagnetic field) as well as the parameters are integer powers of all four fundamental dimensions. Finally, from the physical point of view, electricity is nothing more than electric charges at rest or in motion and as such are the cause of the electric and magnetic fields.

The separation into two dimension systems extending the two mechanical systems into electromagnetics gives *the solution* in so far as avoiding the interference due to the requirements of physics and engineering. In the former field the fundamental units *cm, gram, sec, priestley,* represent the extension of the extremely valuable c.g.s. system into the c.g.s.p. system for electrophysics. On the other hand, the fundamental units *cm, newton, sec, coulomb,* represent the extension of the similarly valuable technical-mechanical system into the c.n.s.c. system. The electrical units employed in the electrotechnical system are all the familiar, so-called "practical" units; while the units employed in the electrophysical system are all of the so-called absolute units, using the latest decisions of the International Electrotechnical Commission.[23] It is surprising to note, that during the last few meetings the International Electrotechnical Commission considered the completion of unit names in the electrophysical system. It is

TABLE V—ELECTROTECHNICAL DIMENSION SYSTEM

Fundamental Dimensions: $[f]$, $[l]$, $[t]$, $[Q]$

Group	Quantity	Symbol	Dimension	Electrotechnical unit	Expressed in electrophysical units
1. (Fundamental)	Length	l	$[l]$	centimeter	1 centimeter
	Time	t	$[t]$	second	1 second
	Force	f	$[f]$	newton = 10.2 kg force	10^7 dynes
	Electric charge	Q	$[Q]$	coulomb	$3 . 10^9$ priestleys
2. (Mechanical)	Energy	W	$[f]\,[l]$	joule = 1 newton cm	10^7 ergs
	Power	P	$[f]\,[l]\,[t]^{-1}$	watt	10^7 ergs/sec
	Mass	m	$[f]\,[l]^{-1}\,[t]^{-2}$	gram-seventh = 10^4 kg	10^7 grams
3. (Electrical)	Electrostatic flux	ψ	$[Q]$	coulomb	$3 . 10^9$ priestleys
	Displacement	D	$[Q]\,[l]^{-2}$	coulomb/cm²	$3 . 10^9$ priestleys/cm²
	Current	I	$[Q]\,[t]^{-1}$	ampere	$3 . 10^9$ priestleys/sec $= \frac{1}{10}$ gilbert
	Current density	G	$[Q][l]^{-2}[t]^{-1}$	ampere/cm²	$\frac{1}{10}$ gilbert/cm²
	Magnetizing force	H	$[Q][l]^{-1}[t]^{-1}$	ampere/cm	$\frac{4\pi}{10}$ oersted $= \frac{1}{10}$ gilbert/cm
	Magnetomotive force	F	$[Q][t]^{-1}$	ampere	$\frac{4\pi}{10}$ oersted cm $= \frac{1}{10}$ gilbert
4. (Electrodynamical)	Magnetic flux	ϕ	$[f][Q]^{-1}[l][t]$	voltsec	$\frac{1}{300}\ \frac{\text{erg sec}}{\text{priestley}} = 10^8$ maxwell
	Induction	B	$[f][Q]^{-1}[l]^{-1}[t]$	voltsec/cm²	10^8 gauss
	Electric field intensity	E	$[f][Q]^{-1}$	volt/cm	10^8 maxwell/cm sec
	Voltage	V	$[f][Q]^{-1}[l]$	volt	10^8 maxwell/sec
5. (Electromagnetic parameters)	Capacitance	C	$[f]^{-1}[Q]^2[l]^{-1}$	farad	10^{-9} sec/kirchhoff
	Absolute dielectric constant	Δ	$[f]^{-1}[Q]^2[l]^{-2}$	farad/cm	10^{-9} sec/kirchhoffcm
	Resistance	R	$[f][Q]^{-1}[l][t]$	ohm	10^9 kirchhoff
	Inductance	L	$[f][Q]^{-2}[l][t]^{-2}$	henry	10^9 kirchhoffsec
	Absolute permeability	Π	$[f][Q]^{-2}[t]^2$	henry/cm	10^9 kirchohffsec/cm

UNIVERSAL CONSTANTS

Absolute dielectric constant of free space: $\Delta_0 = \frac{1}{4\pi} . \frac{1}{9.10^{11}}$ farad/cm $= 0.884 . 10^{-12}$ farad/cm

Absolute permeability of free space: $\Pi_0 = 4\pi . 10^{-9}$ henry/cm $= 1.256.10^{-8}$ henry/cm

necessary, however, that a final agreement be reached between physicists and engineers.

The unit relations contain numerical factors and not factors with dimensions of velocity or any power thereof. This is due to the clear specifications of four fundamental dimensions.

In order to simplify the notations, three new unit names have been suggested: priestley, newton and kirchhoff. Whether or not these names are adopted is irrelevant, but it is necessary that these or other names be chosen to complete the tables. For some time the need has been felt for a unit of force equal to 10.2 *kg-force*,* which provides a simple relation between the technical and physical force units, as well as the respective energy and power units. With respect to the *priestley*, it is obvious that a name should be given to such a fundamental unit of the entire electrophysical system. The *kirchhoff* has been introduced due to its importance for the last group of parameters in Table VI.

It remains to show how the various forms of writing Maxwell's field equations merely depend upon the units employed. Consider, for example, the first field equation in the simplified form:

$$\text{curl}\ \overline{\text{H}} = \overline{\text{G}}. \tag{25a}$$

In the electrotechnical system the units are amp/cm for $\overline{\text{H}}$, amp/cm² for $\overline{\text{G}}$, and no numerical factor is involved. Now, if $\overline{\text{G}}$ is left in amp/cm² and $\overline{\text{H}}$ is given in *oersteds*, Table VI gives the relation

$$1\ \text{oersted} = \frac{10}{4\pi}\ \text{amp/cm},$$

so that

$$\left.\begin{array}{lll} & \text{curl}\ \dfrac{10}{4\pi}\ \overline{\text{H}} = \overline{\text{G}} & \\ \text{or} & \text{curl}\ \overline{\text{H}} = \dfrac{4\pi}{10}\ \overline{\text{G}} & \end{array}\right\} \begin{array}{l} \overline{\text{H}}\ \text{in oersteds,} \\ \\ \overline{\text{G}}\ \text{in amp/cm}^2. \end{array} \tag{25b}$$

In this case, where different units are to be used on the two sides of the equation, it has to be written explicitly as shown in **(25b)**, and a numerical factor enters the equation.

Consider now the complete relation in **(23)** and introduce $\overline{\text{D}}$ in *priestley*/cm². If $\overline{\text{H}}$ is expressed in *oersted*, it is necessary to use the unit relations

---

*This has already been emphasized by V. Karapetoff.[14]

TABLE VI—ELECTROPHYSICAL DIMENSION SYSTEM

Fundamental dimensions: $[m]$, $[l]$, $[t]$, $[Q]$

Group	Quantity	Symbol	Dimension	Electrophysical unit	Expressed in electrotechnical unit
1. (Fundamental)	Length	l	$[l]$	centimeter	1 centimeter
	Time	t	$[t]$	second	1 second
	Mass	m	$[m]$	gram	10^{-7} gram-seventh
	Electric charge	Q	$[Q]$	priestley	$\frac{1}{3} \cdot 10^{-9}$ coulombs
2. (Mechanical)	Energy	W	$[m][l]^2[t]^{-2}$	erg	10^{-7} joule
	Power	P	$[m][l]^2[t]^{-3}$	erg/sec	10^{-7} watt
	Force	f	$[m][l][t]^{-2}$	dyne	10^{-7} newton
3. (Electrical)	Electrostatic flux	ψ	$[Q]$	priestley	$\frac{1}{3} \cdot 10^{-9}$ coulombs
	Displacement	D	$[Q][l]^{-2}$	priestley/cm² $= \frac{1}{3.10^{10}}$ gilbert sec/cm²	$\frac{1}{3} \cdot 10^{-9}$ coulombs/cm²
	Current	I	$[Q][t]^{-1}$	gilbert $= 3.10^{10}$ priestley/sec	10 amperes
	Current density	G	$[Q][l]^{-2}[t]^{-1}$	gilbert/cm²	10 ampere/cm²
	Magnetizing force	H	$[Q][l]^{-1}[t]^{-1}$	oersted $= \frac{1}{4\pi}$ gilbert/cm	$\frac{10}{4\pi}$ ampere/cm
	Magnetomotive force	F	$[Q][t]^{-1}$	gilbert $= 4\pi$ oersted cm	10 ampere
4. (Electrodynamical)	Magnetic flux	ϕ	$[m][Q]^{-1}[l]^2[t]^{-1}$	maxwell $= \frac{1}{3.10^{10}} \frac{\text{erg sec}}{\text{priestley}}$	10^{-8} voltsec
	Induction	B	$[m][Q]^{-1}[t]^{-1}$	gauss	10^{-8} voltsec/cm²
	Electric field intensity	E	$[m][Q]^{-1}[l][t]^{-2}$	maxwell/cm sec	10^{-8} volt/cm
	Voltage	V	$[m][Q]^{-1}[l]^2[t]^{-2}$	maxwell/sec	10^{-8} volt
5. (Electromagnetic parameters)	Capacitance	C	$[m]^{-1}[Q]^2[l]^{-2}[t]^2$	sec/kirchhoff	10^9 farad
	Absolute dielectric constant	Δ	$[m]^{-1}[Q]^2[l]^{-3}[t]^2$	sec/kirchhoff/cm	10^9 farad/cm

	Absolute permeability	Π	$[m][Q]^{-2}[l]$	kirchhoffsec/cm	10^{-9} henry/cm

UNIVERSAL CONSTANTS

Absolute dielectric constant of free space: $\Delta_0 = \frac{1}{4\pi} \frac{\text{priestley}^2}{\text{erg cm}} = \frac{1}{4\pi} \cdot \frac{1}{9.10^{20}}$ sec/kirchhoffcm

Absolute permeability of free space: $\Pi_0 = 4\pi \cdot \frac{1}{9.10^{20}} \frac{\text{erg sec}^2}{\text{priestley}^2\text{ cm}} = 4\pi$ kirchhoff sec/cm

$$1 \text{ priestley/cm}^2 = \frac{1}{3.10^{10}} \text{ gilbert sec/cm}^2$$

$$= \frac{4\pi}{3.10^{10}} \text{ oersted sec/cm,}$$

which lead to

$$\text{curl } \overline{\text{H}} = \frac{4\pi}{10} \overline{\text{G}} + \frac{4\pi}{3.10^{10}} \cdot \frac{\partial \overline{\text{D}}}{\partial t} \qquad \text{(25c)}$$

Where $\overline{\text{H}}$ is in *oersteds*, $\overline{\text{G}}$ in *amp./cm²* and $\overline{\text{D}}$ in *priestleys/cm²*. It appears that the degree of familiarity of the result depends upon the variety of units involved.

D. THE PROBLEM OF A UNIQUE COMPREHENSIVE UNIT SYSTEM

Quite a long series of papers has been devoted during the last three decades to a problem which may be formulated as: *Find, among the "infinity to the fourth" various unit systems* possible in electromagnetics, *a single one* which satisfies all requirements of practicability in all fields of physics, by means of merely taking powers of 10 of the "fundamental units."*

No such system has been found as yet and it would appear that *there is no real need for such a comprehensive system.* The two systems as proposed here may, however, approximate quite closely such a comprehensive system, if the *newton* is introduced as a new force unit. Then the electrical and mechanical quantities are connected by simple relations involving powers of 10, but the mass unit is somewhat large. This objection is not so serious since the mass is only a *derived* unit in the electrotechnical system.

The electrophysical system, with the unfortunate tendency of introducing factors 4π and 3.10^{10} naturally does not involve such simple relations. If there were, however, the possibility of defining a fundamental unit of electric charge as

---

*For information pertaining to the various attempts to solve this problem see references 26, 30, 31, 32, 25, 33, 6, 34, 35.

$$1 \text{ cavendish} = 3 \text{ priestleys},$$

then the factors 3 and 9 or $\frac{1}{3}$ and $\frac{1}{9}$ would disappear in all unit relations but would combine with the universal constants as

$$\left.\begin{aligned} \Delta_0 &= \frac{1}{4\pi} \cdot \frac{1}{9} \frac{\text{cav}^2}{\text{erg cm}} = \frac{1}{4\pi} \cdot \frac{1}{9} \cdot 10^{-11} \text{ farad/cm} \\ \Pi_0 &= 4\pi \cdot 10^{-20} \frac{\text{erg sec}^2}{\text{cav}^2 \text{ cm}} = 4\pi \cdot 10^{-9} \text{ henry/cm.} \end{aligned}\right\} \quad (26)$$

Then, if the unit of magnetizing force be taken as 1 gilbert/cm instead of the new oersted, the relations between the two electrical systems of units would only involve integer powers of 10. This would require that, for free space $k_e = 9 \frac{\text{erg cm}}{\text{cav}^2} = 1 \frac{\text{erg cm}}{\text{priestley}^2}$; or the unit charge 1 *cavendish* would be defined as a charge exerting a force of 9 *dynes* on an equal charge at a distance of 1 *cm;* or a force of 1 *dyne* at a distance of 3 *cm*. Such definitions might not meet with the approval of physicists but they do indicate the possibility of a comprehensive unit system.

CONCLUSION

The absolute dimension systems expressing the electric and magnetic quantities by the 3 dimensions of mechanics have been shown to be incorrect, since the consequent use of proper mathematical statements leads to impossible results. However, the definitions of the absolute units, as well as the practical units in electromagnetics have sense quite independent of the dimension systems. It is shown that the simplest and as it seems apparently, the only true solution, is to extend the two mechanical dimension systems, known as technical and physical systems, into the field of electromagnetics, by adding a new fundamental electric dimension. This gives two electrical systems—the electrotechnical dimension system with all the practical units and the electrophysical dimension system with all the absolute units.

The continuous use of the *absolute* dimension systems in physics as well as electrical engineering textbooks, requires final international action and the proposals summarized in Tables V and VI may be considered as a basis for such action. However, for the present, it would seem desirable to restrict the discussion to the fundamental idea outlined in this paper. The introduction of new unit names and other such details may well be deferred to some later time. The achievement of final international agreement is highly desirable, but such a goal will require the cooperation of physicists and the International Electrotechnical Commission.

ACKNOWLEDGMENT

The author is very much indebted to Mr. H. B. Hanstein of the Department of Electrical Engineering for his very valuable help in improving the English presentation.

Appendix A

THE DIMENSION SYSTEMS IN MECHANICS

Fundamental Measurements:

Distance $[l]$
Time $[t]$

Important Definitions

Velocity $v = \frac{ds}{dt} \therefore [v] = \frac{[l]}{[t]}$

Acceleration $a = \frac{dv}{dt} \therefore [a] = \frac{[l]}{[t^2]}$

Momentum $M = mv \therefore [M] = [m] \frac{[l]}{[t]}$.

Independent Laws in Mechanics:

1. Force on a moving body $f = m \cdot a \therefore [f] = [m] \frac{[l]}{[t^2]}$
2. Gravitation law $f = k \frac{m_1 m_2}{r^2} \therefore [f] = [k] \cdot \frac{[m^2]}{[l^2]}$
3. Kinetic energy $W = \frac{1}{2} mv^2 \therefore [W] = [m] \cdot \frac{[l^2]}{[t^2]}$

Some Dependent Relations:

Force from energy $f = -\frac{\partial W}{\partial s} \therefore [f] = \frac{[W]}{[l]}$

same as (**1**) and (**3**).

Power $P = \frac{dW}{dt} \therefore [P] = \frac{[W]}{[t]}$

From the three independent laws it is seen that 6 dimensions are involved, so that $\binom{6}{3} = 20$ possible *dimension systems* exist.* It would, however, be possible to use any one of the definitions (only few are listed) in order to replace a certain dimension in the laws 1, 2, 3 by a defined dimension. For example, $[l]$ could be replaced by $[v]\ [t]$, thereby obtaining a wider choice of fundamental dimensions. However interesting the result may be, no use will be made of these possibilities at this point.

---

*Since each independent law involves 4 dimensions, this result is correct.

Appendix B

The Dimension Systems in Heat

Fundamental Measurements:

Distance	$[l]$
Time	$[t]$
Temperature	$[\theta]$

Important Definitions:

Force $\quad f = m \cdot a \quad \therefore [f] = [m] \cdot \dfrac{[l]}{[t^2]}$

Pressure $\quad p = \dfrac{df}{dS} \quad \therefore [p] = \dfrac{[f]}{[l^2]}$

$$= \frac{[m]}{[l]\,[t^2]}$$

Energy $\quad H = W = m\dfrac{v^2}{2} \therefore [W] = [m] \cdot \dfrac{[l^2]}{[t^2]}$

Independent Laws in Heat Theory:

1. Boyle-Charles's law for gases

$$p \cdot V = m \cdot R \cdot \theta, \therefore \frac{[l^2]}{[t^2]} = [R] \cdot [\theta]$$

2. Conduction of heat power

$$\frac{dH}{dt} = k \cdot S \cdot \frac{d\theta}{dn} \therefore \frac{[W]}{[t]} = [k]\,[l]\,[\theta]$$

Some Dependent Relations:

Specific heat $\quad H = s \cdot m \cdot \delta\,\theta$

$$\therefore [s] = \frac{[W]}{[m]\,[\theta]} = \frac{[l^2]}{[t^2]\,[\theta]}$$

In the two independent laws given above, 6 dimensions are involved and, therefore, 4 fundamental dimensions are required to form a dimension system in the theory of heat. The upper limit $\dbinom{6}{2} = 15$ dimension systems is not reached here, since the first law only involves 4 dimensions. However, it would be possible to use the definitions in order to replace $[W]$ by either $[f]$ or $[m]$, thereby again extending the choice.

Appendix C

The Dimension Systems in Electromagnetism

Fundamental Measurements:

Distance	$[l]$
Time	$[t]$

Important Definitions:

Force $\quad f = m \cdot a \quad \therefore [f] = [m]\dfrac{[l]}{[t^2]}$

Work $\quad W = \int \bar{\mathbf{f}} \cdot \overline{\mathbf{ds}} \therefore [W] = [f] \cdot [l]$

Independent Laws in Electromagnetism:

1. Coulomb's law* (for two point charges)

$$\bar{\mathbf{f}}_e = \left(k_e \cdot \frac{Q_1}{r^2} \cdot \frac{\bar{\mathbf{r}}}{r}\right) \cdot Q_2 = \bar{\mathbf{E}}_1 \cdot Q_2 \therefore [f]$$

$$= [k_e] \cdot \frac{[Q^2]}{[l^2]}$$

2. Ampere's law* (for two parallel infinitely long wires)

$$\bar{\mathbf{f}}_m = \left[\bar{\mathbf{I}}_2 \times \left(k_m \cdot \frac{\bar{\mathbf{I}}_1}{r} \times \frac{\bar{\mathbf{r}}}{r}\right)\right] \cdot l$$

$$= (\bar{\mathbf{I}}_2 \times \bar{\mathbf{B}}_1) \cdot l \therefore [f] = [k_m] \cdot [I^2]$$

3. Law of conservation of electricity†

$$I = \frac{dQ}{dt}, \qquad \therefore [I] = \frac{[Q]}{[t]}$$

Some Independent Relations:

Faraday's induction law:

$$-\frac{d}{dt}\iint \bar{\mathbf{B}} \cdot \overline{\mathbf{ds}} = \beta \cdot \int \bar{\mathbf{E}} \cdot \overline{\mathbf{ds}} \therefore [k_m] \cdot [I]\frac{[l]}{[t]}$$

$$= [\beta] \cdot [k_e]\frac{[Q]}{[l]}$$

so that: $[\beta] = 1$.

Again there are 3 independent laws as in mechanics, but in this case 7 dimensions are involved so that the highest number of possible dimension systems would be $\dbinom{7}{3} = 35$, each dimension system being composed of 4 fundamental dimensions. However, two of the laws involve only 3 dimensions, so that the number of possibilities is reduced to

$$\binom{3}{2} \cdot \binom{4}{2} = 3 \times 6 = 18.$$

---

*These two laws can also be written as $f_e = k_e \dfrac{Q_1Q_2}{r^2}$ and $f_m = k_m \dfrac{I_1I_2}{r} \cdot l$. In this scalar form the main difference between the two fields described by the laws is not sufficiently emphasized. The electrostatic field is a scalar-potential field, produced by scalar quantities, the electric charges; the magnetostatic field is a vector potential field, produced by vector quantities, the currents. The electric field strength $\bar{\mathbf{E}}$ is a gradient, whereas the magnetic field strength $\bar{\mathbf{B}}$ is a curl. It would seem inadvisable to choose similar mathematical expressions for two physical concepts which are so extremely different.

†This law can be interpreted either as the link between electrostatic charge and the discharge current for a condenser, or as the drift of electrons in metallic conduction.

As in Appendix B, it would be possible to extend the choice of dimension systems by using the definitions given above and expressing $[f]$ in terms of either $[m]$ or $[W]$.

Performance Calculations on Induction Motors

Practical Straightforward Means for Calculating Performance of Single-Phase or Polyphase Induction Motors

C. G. VEINOTT*
Associate, A.I.E.E.

***Synopsis.**—Practical means for calculating the performance of both single-phase and polyphase induction motors from previously determined constants are developed in a straightforward manner. The methods are suitable for accurate calculations but can be simplified for approximate calculations. The methods given are complete and no auxiliary charts or sets of curves are required, nor need any diagram be constructed.*

The single-phase calculation method is based on the cross field theory presented by H. R. West. The polyphase calculation method is based on the equivalent circuit.

I. INTRODUCTION

RECENTLY there have been presented two methods of calculating the performance of polyphase induction motors. One of these was developed by Mr. W. J. Branson[1] and is based upon an analytical solution of a circle diagram, although it might have been based upon an equivalent circuit, and requires about 100 pages of families of curves. The other method was proposed by Mr. P. L. Alger[2] and is based upon the expansion of the impedance of the equivalent circuit into the form of an infinite power series, the number of terms of which are used being dependent upon the accuracy desired. Four or five years ago, Mr. H. R. West[3] developed and proposed a symbolic method for calculating the performance of a single-phase induction motor.

In this paper are presented two calculating methods, one for the performance of single-phase induction motors and one for polyphase induction motors. Both of these methods are developed by means of complex algebra and the finished calculating sheets are quite similar in character. Neither of the methods requires an auxiliary chart, circle diagram, or set of curves, and both methods are believed to have certain distinct and unique advantages over other methods proposed to date.

The basis for the calculating method for polyphase motors proposed in this paper is the equivalent circuit of Fig. 2 and no new theories or concepts are introduced. This method can be followed to give exactly the same identical results in every respect as this equivalent circuit, for any and all values of any of the given constants. Such exactness, however, is ordinarily not necessary, and virtually all other methods which have been proposed previously as practicable contain one or more simplifying approximations, some methods making one approximation and some another.

It is unfortunate, however, that what may be safe approximations for one motor may be quite inadequate for another motor; *e. g.*, the influence of primary resistance on the primary current can usually be neglected in large motors but not in small motors. Moreover, in some cases it is desirable to make a number of approximations in order to obtain rough results quickly, and in other cases, more exact results are needed and a greater expenditure of time is justifiable.

The calculation method presented in this paper is so arranged and described that the Steinmetz equivalent circuit of Fig. 2 can be followed with absolute exactness or with varying degrees of approximation as desired, the approximations resulting in a saving in labor in calculating the constants for applying the method but not changing the general scheme of the method. This feature is felt to possess very distinct advantages also, the fact that it is neither necessary to construct a circle diagram nor to use any auxiliary charts is a not-to-be-over-looked advantage.

The single-phase calculation sheet offers, though to a more limited extent, the same general advantages as does the polyphase calculation sheet.

Since the purpose of this paper is only to present a simple, straightforward method of calculating the performance of either a single-phase or a polyphase induction motor and not to introduce any new or unfamiliar concepts, the paper itself deals only with the methods themselves, the assumptions upon which they are based, and how to make practical use of them. These methods can only be applied after the constants of the motor have been determined either from design constants, or by test, or by any other suitable means. The determination of these constants is a sufficient problem in itself and one with which this paper will not be concerned. The developments of the calculating methods are recorded in Appendixes II and III.

II. NOTATION

Before proceeding with an explanation of the calculation sheet, the constants appearing on these sheets will be briefly summarized and discussed.

E = impressed volts per phase

r_1 = primary resistance per phase

r_2 = secondary resistance per phase referred to the primary

---

*Small Motor Engg. Dept., Westinghouse Elec. & Mfg. Co., Springfield, Mass.

1. For references see Bibliography.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

r_f = resistance representing core loss when connected in parallel with X_m

r_m = resistance representing core loss when connected in series with X_m

x_1 = primary leakage reactance per phase

x_2 = secondary leakage reactance per phase referred to the primary

Xm = magnetizing reactance per phase

X = ideal short-circuit reactance of motor ($r_2 = 0$)

$$= x_1 + x_2 \frac{Xm}{Xm + x_2}.$$

This is the reactance the motor would have with short-circuited secondary if the iron loss and secondary resistance were zero. This expression, however, does take into account the shunting of the secondary leakage reactance by the magnetizing reactance

Xo = $Xm + x_1$ = reactance of the primary winding with the secondary open-circuited

$$Kp = \frac{Xm}{Xo} = \sqrt{\frac{Xo - X}{Xo}} \text{ (used only when } x_1 = x_2\text{)}$$

I_1* = primary current per phase

I_2 = secondary current per phase for polyphase motors—secondary current in transformer axis for single-phase motors

I_3 = secondary current in cross field axis (single-phase motors only)

Im = total current in branch of equivalent circuit representing core loss and magnetizing current, (polyphase motors only)

Io = no-load current per phase

$$i_m = \frac{E}{Xo}$$ = primary current per phase which would flow if secondary were open-circuited, either single-phase or polyphase motors, (in polyphase motors $i_m = Io$, approximately)

$$S = \frac{\text{actual speed}}{\text{synchronous speed}}$$ (used with single-phase motors)

$$s = \frac{\text{slip r.p.m.}}{\text{synchronous r.p.m.}}$$ (used with polyphase motors)

ϕ = number of phases

Torque. The formulas for torque given in this paper are for torque in oz-ft. These formulas may be changed to give torque in other units by substituting for the quantity 112.6, the following quantities:

For lb-ft.—7.04

For kg-meters—0.974

III. Single-Phase Induction Motor Performance Calculations

Theoretical Basis

In the development of the calculating method for single-phase induction motors, extensive use has been made of West's[2] theory. The assumptions upon which this calculating method is based are thus similar to his in many respects. The angle of hysteretic lag between flux and m.m.f. is neglected, and the magnetomotive force or current required to produce a certain flux is assumed to be proportional to the flux just as in his paper. Sinusoidal voltages and currents, of course, are also assumed.

The general basis of these methods is that the voltage equations for each of the three circuits (shown in Fig. 6) *viz.*, the primary circuit, the transformer field circuit in the secondary, and the cross field secondary circuit, are set up in accordance with Kirchhoff's law. The solution of these three simultaneous equations yields expressions for the currents in each one of these circuits. From these currents and the known reactances of the motor, the fluxes, hence torque and mechanical power developed by the rotor, are obtained. This developed mechanical power is item 30 on the calculation sheet, Fig. 1.

From this point on, the treatment differs somewhat from West's method. From the power developed by the rotor is subtracted the friction and windage and the iron loss due to the cross field. (The cross field loss is assumed to be half or slightly less than half the total iron loss.) The main field iron loss is assumed to be supplied directly from the stator circuit. This is a logical procedure when the motor is considered from the standpoint of the cross field theory,[3] though to be strictly correct, it should be remembered that the core loss is due, not to the separate effects of components of flux, but to the actually existing resultant flux.

As stated before, the main field iron loss is assumed to be supplied directly from the primary power supply, and the stator current is corrected for this additional current to supply the iron loss. This correction is item 14 on the calculating sheet. The input watts are obtained by adding the primary and secondary copper losses and main field iron loss to the developed mechanical output. Power factor and efficiency can then be figured in a conventional manner. It is highly desirable to determine the efficiency by summation of the losses as this at once tells the designer how the losses are distributed in the machine.

Since, in this method of calculation, speed is the independent variable, some means for determining the speed at maximum torque are necessary. In order to accomplish this, use was made of a Branson[4] diagram for single-phase motors as shown in Fig. 7, to determine a general analytical expression for the speed at pull-out as a function of r_2/X, upon which factor the pull-out speed principally depends. The pull-out speed has been

---

*Note: I_1, I_2, I_3, and I_m represent currents which vary with load; I_o and i_m, for any given motor, remain constant.

FIG. 1—PERFORMANCE CALCULATIONS ON A SINGLE-PHASE INDUCTION MOTOR

plotted against r_2/X on Fig. 1 and this method has been found to give generally good results as the error in pull-out speed can be quite large without materially effecting the pull-out torque.

This curve of pull-out speed against r_2/X was calculated for values of the latter up to 2.4 and approached an asymptote of 0.7, indicating that 70 per cent of synchronous speed is the lowest speed at which the pull-out torque of a single-phase induction motor can be made. It is, however, possible to lower the speed at pull-out somewhat below this value by unusual design, though it is not possible to obtain anything like the same control over it as is obtained over the pull-out speed in polyphase motors.

Simplified Calculation Sheet

On the calculating sheet, Fig. 1 it has been further assumed that the primary and secondary reactances were equal, *i. e.*, $x_1 = x_2$. This assumption is not absolutely necessary, as will be shown subsequently, but it is usually justifiable and greatly simplifies matters.

The use of this calculation sheet will be illustrated by means of an example. A 110-volt, 60-cycle, 4-pole squirrel-cage motor was picked at random and the values of E, X, Xo, r_1 and r_2 entered on the sheet. The total core loss for this motor was 19 watts which was arbitrarily distributed, 10 watts to the main field (entered in item 29) and 9 watts to the cross field, which, added to the 10 watts friction and windage, gave 19 watts for the cross field loss plus friction and windage (item 32). From the given constants, Kp etc., and the F constants were figured.

The next step is to select the speed at which the performance characteristics are desired. If the full load performance be desired, the full load slip should be estimated. Thus, it will usually be more satisfactory to attempt to estimate the quantity $1 - S^2$, which is approximately twice the slip for small slips. Just what value of $1 - S^2$ to assume is best governed by experience, as this depends generally upon the size of the motor, ratio of maximum to full load torque, etc. Ordinarily, a value somewhere between 0.05 and 0.08 may be assumed for $1 - S^2$.

In this particular case, 0.075 was assumed for $1 - S^2$, and the output for this value of $1 - S^2$ was figured by computing items 1-10, 23-25, 30 and 33. It will be observed that it is not necessary to figure all the items if only the output is desired. Those items which are necessary are marked by an asterisk in the extreme right hand column. (For a short cut to computing item 10, see Appendix I.)

Now that the output has been found for this motor for a particular value of $1 - S^2$, the full load speed or slip can be estimated with sufficient accuracy for the output can be assumed to be proportional to the quantity $S^2(1 - S^2)$. Using this principle, the full load speed can now be approximated very closely. In the example chosen, an output of 108.5 watts corresponds to a value of $0.925 \times 0.075 = 0.0694$ for the quantity $S^2(1 - S^2)$. The value of the latter quantity for an output of 124.3 watts (full load) is, therefore, by direct proportion, 0.0796. The corresponding value of $1 - S^2$ can be figured from any known value of $S^2(1 - S^2)$ by means of the equation

$$1 - S^2 = \frac{1 - \sqrt{1 - 4\,[S^2(1 - S^2)]}}{2} \qquad \textbf{(41)}$$

In the chosen example, this becomes

$$1 - S^2 = \frac{1 - \sqrt{1 - 4 \times 0.0796}}{2} = 0.087$$

which is the value of $1 - S^2$ corresponding to full load. (Actually $1 - S^2$ may be more readily determined from the quantity $S^2(1 - S^2)$ on a slide rule without the use of the formula given.)

Using 0.087 as the value of $1 - S^2$, the complete performance was calculated by computing items 1 to 38 inclusive. The performance of this same motor was also calculated by means of Branson's[4] circle diagram and the results given in the third column.

The maximum torque was obtained by noting from the curve that the pull-out speed for this motor ($r_2/X = 0.56$) was approximately 0.81 and figuring the torque at this speed.

No-Load Conditions. The no-load currents can be checked approximately by taking $S = 1.0$. With this assumption, the no-load primary current becomes approximately

$$I_0 = \frac{F_4}{F_1} = \frac{2}{2 - K_p^2}\, i_m \qquad \textbf{(42)}$$

and the secondary current, in either axis, becomes

$$I_2 = I_3 = \frac{F_5}{F_1} = \frac{K_p}{2 - K_p^2}\, i_m \qquad \textbf{(43)}$$

The no-load input can then be estimated by adding friction and windage, iron losses, and copper losses due to the currents given by the above expressions. Calculation of no-load current and watts is illustrated in Fig. 1.

For working up constants from test, the following relations obtained from equation (**42**) are useful

$$\left.\begin{aligned} I_0 &= \frac{2E}{Xo + X} \\ Xo &= \frac{2E}{I_0} - X \\ Xm &= XoKp = \sqrt{Xo^2 - XXo} \end{aligned}\right\} \qquad \textbf{(44)}$$

Performance Calculations When x_1 Differs From x_2

The procedure to be followed in this case differs only in the computation of the "F constants." The reactances which must be known are x_1, x_2, and Xm. In Table I are listed the values of the "F constants" in

TABLE I—"A CONSTANTS" AND "F CONSTANTS" FOR SINGLE-PHASE MOTORS

F constant	A constant	Expression for constant $x_1 \neq x_2$	Expression for constant $x_1 = x_2$
F_1	A_1	$r_2\left[\frac{x_2 X_m - r_1 r_2}{(X_m + x_2)^2} + \frac{X_m + 2x_1}{X_m + x_2}\right]$	$r_2\left[\frac{X_0 + X}{X_0} - \frac{r_1 r_2}{X_0^2}\right]$ or $r_2\left[2 - K_p^2 - \frac{r_1 r_2}{X_0^2}\right]$
F_2	$-A_3$	$r_2\left[\frac{r_2(X_m + x_1)}{(X_m + x_2)^2} + \frac{2r_1}{X_m + x_2}\right]$	$(2r_1 + r_2)\ (r_2/X_0)$
F_3	$-A_5$	$E\left(\frac{r_2}{X_m + x_2}\right)^2$	$(i_m r_2)\ (r_2/X_0)$
F_4	$-A_7$	$\frac{2Er_2}{X_m + x_2}$	$(i_m r_2)\ 2$
F_5	$-A_9$	$\frac{EX_m r_2}{(X_m + x_2)^2}$	$(i_m r_2)\ K_p$
F_6	$-A_{11}$	$\frac{E^2 r_2^3 X_m^2}{(X_m + x_2)^4}$	$[(i_m r_2)\ K_p]^2\ r_2$
F_7	A_8	$\frac{EX_m}{X_m + x_2}$	EK_p
F_8	A_{10}	$\left(\frac{EX_m}{X_m + x_2}\right)^2 r_2$	$(EK_p)^2\ r_2$
F_9	A_{12}	$\frac{Fe \text{ loss } (m)}{E}$	$\frac{Fe \text{ loss } (m)}{E}$
	A_4	$x_1 + x_2 \frac{X_m}{X_m + x_2}$	X
	A_2	r_1	r_1
	A_6	E	E

terms of these reactances. (No attention need be paid to the "A constants" as these were merely used in deriving the methods.) In place of X appearing among the given data and in item 7, Fig. 1, should be entered the value of A_4, which is the short-circuit reactance.

For the sake of comparison, the reactance of the motor in the chosen example was assumed to be unequally distributed, 60 per cent of the reactance being in the primary. The "F constants" were computed from the formulas given in Table I and used in the same manner as previously. The final results were found to agree within one per cent.

General Remarks

In general, the above method gives quite satisfactory results. This method is especially convenient when only a part of the performance is desired. For example, if a speed torque curve be desired, only the same items used to figure the maximum torque need be figured. When figuring a speed torque curve, the cross field iron loss and friction should be made to decrease to zero with the speed; otherwise a following of the calculation sheet would result in a negative torque at zero speed. For want of better information, it is suggested when figuring torques below pull-out, that item 32, as given on the sheet, be multiplied by S^2.

Sometimes power factor or efficiency in themselves are unimportant, but the apparent efficiency or full-load current is wanted. In this case, all that need be figured in addition to the output are items 11-17 inclusive, giving the primary output at that point. The apparent efficiency, of course, is

$$\text{apparent efficiency} = \frac{\text{output watts}}{EI_1} \qquad (45)$$

For rough calculations on large motors where the primary resistance is small, the effect of the latter on the primary current can easily be neglected by taking r_1 equal to zero.

IV. POLYPHASE INDUCTION MOTOR PERFORMANCE CALCULATIONS

Theoretical Basis

The generally accepted form of equivalent circuit representing the performance of a polyphase induction motor is as shown in Fig. 2, and this is the circuit proposed by Steinmetz and used by Mr. Alger in his recent paper. In this circuit, the iron loss is represented by a resistance in parallel with the magnetizing reactance. Mr. Branson, in his recent paper,[1] represents the iron loss by a resistance, r_f, connected just inside the primary resistance.

The equivalent circuit of Fig. 2 can be reduced to the form shown in Fig. 3 which is exactly equivalent to that of Fig. 2 if the following values are chosen for r_m and X_m, where r_f and X_m' are taken from the circuit of Fig. 2

$$r_m = \frac{r_f X_m'^2}{r_f^2 + X_m'^2} = \frac{X_m'^2}{r_f} \times \frac{1}{\left[1 + \left(\frac{X_m'}{r_f}\right)^2\right]} \tag{46}$$

$$X_m = \frac{r_f^2 X_m'}{r_f^2 + X_m'^2} = X_m' \times \frac{1}{\left[1 + \left(\frac{X_m'}{r_f}\right)^2\right]} \tag{47}$$

The first approximation made in this paper is that the term in brackets in equations (**46**) and (**47**) is assumed equal to unity. With ordinary motors, this assumption merely means a difference of one or two per cent in reactance only of the core loss and magnetizing branch of the equivalent circuit, but means an appreciable saving in labor when calculating performance.

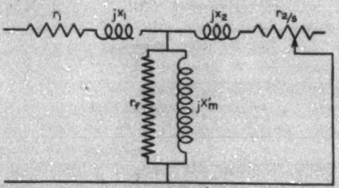

FIG. 2—STEINMETZ EQUIVALENT CIRCUIT OF A POLYPHASE INDUCTION MOTOR

Usually the constants of a motor corresponding to the circuit of Fig. 2, are not known with sufficient accuracy to make a distinction between X_m' and X_m. If desired, however, and r_f and X_m' are known, r_m and X_m can be calculated by means of equations (**46**) and (**47**) and applied directly. In this paper, however, r_m is calculated by the simpler formula

$$r_m = \frac{\text{Core loss}}{\phi \times i_m^2} \tag{48}$$

The method of deriving the calculation method was briefly as follows. Expressions for the primary and secondary currents in terms of the constants of the motor and slip were obtained by ordinary circuit analysis. The mechanical power developed by the secondary, or the secondary output is

$$I_2^2 r_2 \phi \times \frac{1-s}{s} \tag{49}$$

This appears as item 20 on the calculation sheet, Fig. 5. Subtraction of the friction and windage from the secondary output gives the output of the motor. The input is obtained by adding the core loss, the secondary and primary copper losses to the secondary output. The core loss is assumed constant so that this summation gives a slightly higher input than would be obtained by strictly following the equivalent circuit. To follow this equivalent circuit exactly, the copper loss in the resistance r_m can be calculated for each load point and used in place of the core loss. To do this, it is necessary to calculate I_m for each load point. For any load point, I_m is given by

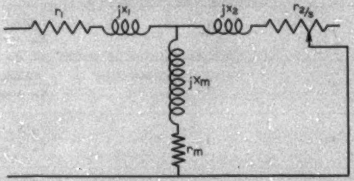

FIG. 3—ANOTHER FORM OF CIRCUIT OF FIG. 2

$$I_m = -\frac{\sqrt{(12)^2 + A_{10}^2}}{(10)^*} \tag{50}$$

where A_{10} has the value given in Table II. I_m could thus be figured and for each individual load point, and the quantity $\phi I_m^2 r_m$ entered in item 19 instead of the core loss, and thus the input obtained would be exactly the same as the power input to the equivalent circuit (real component of $\phi \times \check{E} \times$ conjugate of $\check{I}_1$).

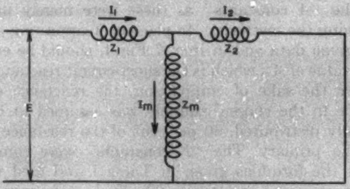

FIG. 4—GENERALIZED FORM OF EQUIVALENT CIRCUIT OF THE POLYPHASE INDUCTION MOTOR

Simplified Calculation Sheet of Fig. 5

In deriving the simplified calculation method of Fig. 5, a further assumption has been made—namely, that the primary reactance equals the secondary reactance. The calculation sheet is virtually self-ex-

---

*(12) and (10) refer to items 12 and 10 in Fig. 5.

TABLE II—"A CONSTANTS" AND "F CONSTANTS" FOR POLYPHASE MOTORS

F constant	A constant	Expression for constant $x_1 \neq x_2$	Expression for constant $x_1 = x_2$
F_1	$-A_1$	$x_1 + x_2 \dfrac{X_m}{X_m + x_2} - \dfrac{r_1 r_m}{X_m + x_2}$	$X - \dfrac{r_m}{X_0} r_1$
F_2	A_4	$\dfrac{(X_m + x_1) r_2}{(X_m + x_2)}$	r_2
F_3	A_2	$\dfrac{(r_1 + r_m) r_2}{X_m + x_2}$	$r_2 \left(\dfrac{r_1 + r_m}{X_0} \right)$
F_4	A_3	$\dfrac{r_m (x_1 + x_2)}{X_m + x_2} + r_1$	$r_1 + \dfrac{2}{1 + K_p} \dfrac{r_m X}{X_0}$ or $r_1 + \dfrac{r_m}{X_0} X$
F_5	A_5	$\dfrac{E r_m}{X_m + x_2}$	$i_m r_m$
F_6	A_6	$\dfrac{E r_2}{X_m + x_2}$	$i_m r_2$
F_7	A_9	$\dfrac{E \sqrt{r_m^2 + X_m^2}}{X_m + x_2}$	$E \sqrt{K_p^2 + \left(\dfrac{r_m}{X_0} \right)^2}$ or $E K_p$
	A_7	E	E
	A_8	$\dfrac{E X_m}{X_m + x_2}$	$E K_p$
	A_{10}	$\dfrac{E x_2}{X_m + x_2}$	$\dfrac{i_m X}{1 + K_p}$

planatory. The known constants of the motor, namely, E, X, X_o, K_p, r_1, r_2, friction and windage and core loss are entered at the left side of the sheet in the spaces provided. The F constants are then computed from these given constants. The slip at which the performance is desired is assumed in item 1. In order to get the output, it is unnecessary to figure each item. Only those items marked by an asterisk are necessary for determination of the output corresponding to the assumed slip. If the first value of slip assumed gives nearly full load output, the next value of slip can be found by assuming the output proportional to the slip. (A useful short cut for figuring items 10 and 14 is described in Appendix I.)

The slip at maximum torque can be found from the expression

$$s_m = \frac{r_2}{\sqrt{r_1^2 + X^2}} \tag{40}$$

Maximum torque is, of course, the torque figured at this slip and starting torque is the torque figured for a slip of unity. The formula given in item 26 can not be used for starting torque since both the output and speed are zero, but starting torque is readily found by putting $s = 1$ in equation (35), Appendix III, obtaining

$$\text{starting torque} = \frac{112.6}{\text{syn. r.p.m.}} I_2^2 r_2 \phi$$

$$= \frac{112.6}{\text{syn. r.p.m.}} \times (18)\ s = 1 \tag{51}$$

The use of this calculation is illustrated by means of a numerical example.

Performance Calculation When x_1 Differs From x_2

If x_1, x_2 and X_m are known, the "F constants" should be calculated in terms of the latter by using the suitable expressions from Table II. It can then be forgotten how the "F constants" were obtained and the performance calculated exactly as shown in Fig. 5.

If it is desired, an equivalent circuit of the form of Fig. 2 can be used as a basis for the calculation of the performance by first reducing it to a circuit of the form of Fig. 3 by means of equations (**46**) and (**47**). Moreover, the core loss can be assumed to vary with load exactly as does the copper loss in the resistance representing core loss in the equivalent circuit by calculating A_{10} and following the process just described.

Approximate Calculations

In addition to the approximations mentioned, other assumptions can be made to simplify calculations for rough work. The calculation sheet is so arranged, for example, that either the primary resistance or iron loss can be neglected by putting r_1 or r_m or both equal to zero.

V. CONCLUSIONS

In this paper, practical methods for calculating the performance of both single-phase and polyphase motors have been developed by straightforward means. Either calculating method consists of the filling in of the blank spaces of a calculation sheet especially prepared for this purpose. The performance can easily be calculated roughly or with practically any desired degree of accuracy by the expenditure of a trifle more labor, depending upon the accuracy with which the constants of the motor are known. The methods are thus suited for either rough design calculations or for more refined calculations, the same form being used for either, the use of the same form for either type of calculation being a distinct advantage.

Moreover, neither of the methods presented in this paper requires the constructing of a circle diagram nor any auxiliary charts or sets of families of curves.

The author wishes gratefully to acknowledge helpful suggestions from Messrs. C. R. Boothby, E. P. Codling, and H. E. Ellis.

Appendix I

There is a method, the origin of which is somewhat uncertain, of evaluating the square root of the sum or difference of two squares which so simplifies this operation for slide rule calculations as to make it well worth a description here since this operation is performed several times in the calculating methods described in this paper.

E = volts per phase = 127

ϕ = no. of phases = 3

X = s. c. reactance (per ph.) = 5.0

X_0 = o. c. reactance (per ph.) = 98.0

$K_p = \sqrt{\dfrac{X_0 - X}{X_0}}$ = 0.970

Friction and windage (watts) = 20

i_m = no load amps = E/X_0 = 1.297

Core loss (total) = 37

$r_m = \dfrac{\text{core loss}}{\phi \times i_m^2}$ = 7.32

r_1 = pri. res. per phase = 2.40

$F_2 = r_2$ = 1.55

$F_3 = r_2 \dfrac{r_1 + r_m}{X_0}$ = 0.1537

$F_1 = X - \dfrac{r_m}{X_0} r_1$ = 5.82

$F_4 = r_1 + \dfrac{r_m}{X_0} X$ = 2.85

$F_5 = i_m r_m$ = 9.49

$F_6 = i_m r_2$ = 2.01

$F_7 = EK_p$ = 123.2

Stg. torque = $\dfrac{112.6}{\text{syn. r.p.m.}} \times (18)_{s=1}$ (in oz-ft.)

Slip at max. torque = $s_m = \dfrac{r_2}{\sqrt{r_1^2 + x^2}}$ = 0.240

FIG 5—PERFORMANCE CALCULATIONS ON A POLYPHASE INDUCTION MOTOR

Assume that we wish to evaluate $\sqrt{a^2 + b^2}$. By simple algebra

$$\sqrt{a^2 + b^2} = a\sqrt{1 + \left(\frac{b}{a}\right)^2}$$

Either b or a may be the larger, but it will generally be easier to divide the larger number by the smaller one.

To illustrate, let us evaluate $\sqrt{2.34^2 + 6.29^2}$. Divide 6.29 by 2.34 using the C and D scales. The square of the quotient, $\left(\frac{b}{a}\right)$, is located under the left index of the B scale which reads 7.22. Add one mentally, obtaining 8.22. Move the slide until the left index of the B scale is opposite 8.22. Now, move the runner to the smaller number or 2.34 on the C scale and read 6.72, which is the desired result, on the D scale. The method is simpler to apply than explain. Similarly, the square root of the difference between two squares can be determined by subtracting one mentally from the square of the quotient of the larger number by the smaller one, extracting the square root and multiplying this root by the smaller number.

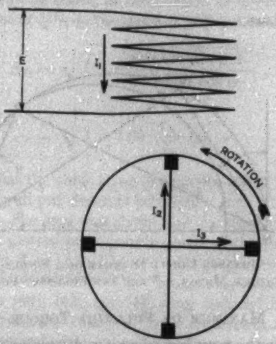

FIG. 6—THE SINGLE-PHASE INDUCTION MOTOR VIEWED FROM THE CROSS FIELD BASIS

Appendix II

THEORY OF THE SINGLE-PHASE MOTOR

Determination of the Currents. A single-phase motor can be represented diagrammatically as shown in Fig. 6.

Using Kirchhoff's law that the applied voltage must equal the impedance drops, Mr. West writes, for the primary,

$$E = r_1I_1 + jx_1I_1 + jX_m(I_1 - I_2) \quad (1)$$

Similarly, in the rotor, the sum of all the induced voltages in each circuit must independently be equal to zero, giving the following two equations:

$$-jX_m(I_1 - I_2) - S(X_m + x_2)I_3 + r_2I_2 + jx_2I_2 = 0 \quad (2)$$

$$j(X_m + x_2)I_3 - SX_m(I_1 - I_2) + Sx_2I_2 + r_2I_3 = 0 \quad (3)$$

These three equations can be re-arranged and solutions readily obtained for I_1, I_2, and I_3 by means of determinants. The determinant for the common denominator reduces to

$$U_1 + jW_1$$

Where

$$\begin{aligned} U_1 = & -r_1r_2^2 + 2r_2x_1(X_m + x_2) + r_2X_m(X_m + 2x_2) \\ & + (1 - S^2)\,r_1(X_m + x_2)^2 \end{aligned} \quad (4)$$

$$\begin{aligned} W_1 = & -r_2^2x_1 - 2r_1r_2(X_m + x_2) - r_2^2X_m \\ & + (1 - S^2)\left[x_1(X_m + x_2)^2 + x_2X_m(X_m + x_2)\right] \end{aligned} \quad (5)$$

The numerator of I_1 is

$$E\left[-r_2^2 + (1 - S^2)(X_m + x_2)^2 - j2r_2(X_m + x_2)\right] \quad (6)$$

The numerator of I_2 is

$$EX_m\left[(1 - S^2)(X_m + x_2) - jr_2\right] \quad (7)$$

The numerator of I_3 is

$$-SEX_mr_2 \quad (8)$$

To make calculations on different motors more nearly alike, it is best as Mr. West points out, to divide equations (4) to (8) by $(X_m + x_2)^2$ obtaining the following expressions for the three currents

$$I_1 = \frac{A_5 + (1 - S^2)A_6 + jA_7}{U + jW} \quad (9)$$

$$I_2 = \frac{A_8(1 - S^2) + jA_9}{U + jW} \quad (10)$$

$$I_3 = \frac{A_9S}{U + jW} \quad (11)$$

Where

$$\begin{aligned} U &= A_1 + A_2(1 - S^2) \\ W &= A_3 + A_4(1 - S^2) \end{aligned} \quad (12)$$

and A_1, A_2, etc., have the values given in Table I. Equations (10) and (11) are the basis for items 20 and 22 on the calculation sheet. The primary current, however, is obtained from equation (18).

Output. Mr. West shows that the net torque in synchronous watts developed by the rotor is, in the symbols of this paper

Torque (in synchronous watts)

$$= \frac{E^2X_m^2r_2S\left[(1 - S^2)(X_m + x_2)^2 - r_2^2\right]}{U_1^2 + W_1^2} \quad (13)$$

$$= \frac{S(1 - S^2)A_{10} + SA_{11}}{U^2 + W^2} \quad (14)$$

Where A_{10} and A_{11} have the values given in Table I. The mechanical power developed by the rotor, exclusive of core loss and friction and windage is, therefore:

$$\text{power developed in watts} = \frac{(1 - S^2)\, A_{10} + A_{11}}{U^2 + W^2} \times S^2 \qquad (16)$$

This equation is the basis for item 30 on the single-phase calculation sheet, Fig. 1A. From this quantity is subtracted the cross field iron loss and friction and windage to obtain the output. The input is obtained by adding to the former quantity the main field iron loss and the primary and secondary copper losses.

Correction of Primary Current for Main Field Core Loss. In order to correct the primary current for the main field core loss, it is assumed that slightly more than half the core loss is supplied directly from the stator power supply. The method of accounting for the core loss cannot be illustrated directly either by a diagram or by an equivalent circuit. The iron loss is considered as being supplied by an in-phase component of current which flows through the primary circuit. This in-phase component of current which supplies the main field core loss is

$$A_{12} = \frac{\text{main field iron loss}}{E} \qquad (17)$$

Adding this current to I_1 as given in equation (**9**), gives for the primary current corrected for iron loss

$$I_1 = \frac{A_5 + (1 - S^2)\, A_6 + A_{12}U + j\,(A_7 + A_{12}W)}{U + jW} \qquad (18)$$

It will be found, however, that in normal motors, W is usually small compared with U up to well above full load, so that for all practical purposes, the effect of the term A_{12} on I_1 cannot be found in ordinary slide rule computations, and it is therefore justifiable to neglect it. On the calculation sheet, the primary current is figured from equation (**18**), neglecting the term $A_{12}W$.

Simplification of the Constants. If the leakage reactance be assumed to be equally divided between the primary and secondary, the constants A_1 to A_{12} inclusive can be reduced to expressions very much easier to calculate numerically, and the final results will be little different than if account were taken of the actual distribution of leakage. In the majority of cases, the amount of leakage chargeable to the primary and that to the secondary is not accurately known since no method has yet been devised to separate these leakages by an actual test. It is therefore justifiable, for ordinary purposes, to assume the $x_1 = x_2$. The reactance of the primary with the secondary open-circuited will be, therefore

$$X_m + x_1 = X_m + x_2 = X_0 \qquad (19)$$

The short-circuit reactance of the motor, taking into account the shunting of the secondary leakage by the magnetizing reactance is

$$x_1 + x_2 \frac{X_m}{X_m + x_2} = x_2 + x_1 \frac{X_m}{X_m + x_1} = X \qquad (20)$$

From the above relations, a further interesting relation can be shown to be exactly true when $x_1 = x_2$

$$\frac{X_m}{X_0} = \sqrt{\frac{X_0 - X}{X_0}} = K_p \qquad (21)$$

The primary current with the secondary open is

$$i_m = \frac{E}{X_0} \qquad (22)$$

Using equations (**19**) to (**22**) the values obtained for the A constants can be much simplified as shown in Table I. In expressions in this table, no approximations have been made although on the calculation sheet the term $-\dfrac{r_1 r_2}{X_0}$ has been dropped from F_1 as it is insignificant here.

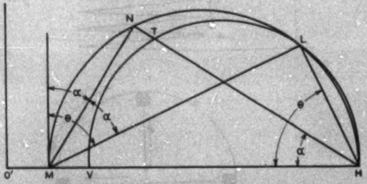

Fig. 7—Branson Circle Diagram of a Single-Phase Induction Motor, Locked and Pull-Out Points

MAXIMUM OR PULL-OUT TORQUE

Perhaps the most logical way to determine the maximum torque would be to write for the developed or internal torque, the following expression from (**16**)

$$\text{Internal torque} = \frac{112.6 \times S}{\text{syn. r.p.m.}} \times \frac{(1 - S^2)\, A_{10} + A_{11}}{U^2 + W^2} \qquad (23)$$

differentiate it with respect to S and equate to zero to obtain the speed at maximum torque. Such a procedure, however, leads to a sixth degree equation (really a third degree equation as only the even powers of S exist) which is too cumbersome for practical use. Since it is not necessary to know the speed at pull-out with a high degree of accuracy in order to obtain the maximum torque sufficiently close, the following alternative method was used to obtain the speed at pull-out.

Fig. 7 shows a typical Branson circle diagram of a single-phase motor. $O'M = i_m$, $O'V$ no-load current and $O'H$ the locked current, also $< LMH = \tan^{-1} \dfrac{r_2}{X}$. For any load point T, the speed, as a fraction of synchronous speed is, from Branson

$$S = \sqrt{\frac{TH - MNr_2/X}{TH}} = \sqrt{1 - \frac{MNr_2/X}{TH}} \qquad \textbf{(24)}$$

The point T for maximum torque is taken so that the line NH bisects the arc VL. This amounts to the same thing as bisecting the arc ML. We can now calculate MN and NH as follows for

$$\theta = \cot^{-1} \frac{r_2}{X} \text{ (complement of } < LMH)$$

$$\alpha = \frac{\theta}{2} = \frac{1}{2} \cot^{-1} \frac{r_2}{X} \qquad \textbf{(25)}$$

and

$$MN = MH \sin \alpha$$
$$NH = MH \cos \alpha$$

but TH can be taken, in most cases, as approximately 95 per cent of NH, so the speed at pull-out becomes

$$S_{po} = \sqrt{1 - \frac{(MH \sin \alpha)\, r_2/X}{0.95\, MH \cos \alpha}}$$

$$= \sqrt{1 - 1.05 \frac{r_2}{X} \tan \alpha} \qquad \textbf{(26)}$$

where α has the value given in equation (**25**). Thus, the speed at pull-out depends principally upon r_2/X. The value of *Spo* was calculated for different values of r_2/X and plotted on the curve given on the calculation sheet, Fig. 1.

No-Load Conditions. The various relations given in equations (**42**), (**43**), and (**44**) were deduced by simple algebra from the values of the F constants and need not be repeated here.

Appendix III

THEORETICAL BASIS OF POLYPHASE CALCULATION SHEET

Fig. 4 shows the more general form of equivalent circuit for either Fig. 2 or Fig. 3. The currents, in terms of the impedances, are:

$$I_1 = \frac{E\,(Z_m + Z_2)}{Z_1 Z_m + Z_1 Z_2 + Z_2 Z_m} \qquad \textbf{(27)}$$

$$I_2 = \frac{E Z_m}{Z_1 Z_m + Z_1 Z_2 + Z_2 Z_m} \qquad \textbf{(28)}$$

$$I_m = \frac{E Z_2}{Z_1 Z_m + Z_1 Z_2 + Z_2 Z_m} \qquad \textbf{(29)}$$

It is now a simple matter to substitute the individual resistances and reactances in the above equations. For the sake of convenience in numerical computations, it will be found highly desirable to divide numerators and denominators by the quantity $(X_m + x_2)$. This done, the following equations are obtained

$$I_1 = \frac{A_5 + A_6/s + jA_7}{U + jW} = \frac{F_5 + F_6/s + jE}{U + jW} \qquad \textbf{(30)}$$

$$I_2 = \frac{A_5 + jA_8}{U + jW} = \frac{F_7}{\sqrt{U^2 + W^2}} \text{ (numerically)} \qquad \textbf{(31)}$$

$$I_m = \frac{A_6/s + jA_{10}}{U + jW} \qquad \textbf{(32)}$$

where

$$U = A_1 + A_2/s = F_3/s - F_1 \qquad \textbf{(33)}$$
$$W = A_3 + A_4/s = F_4 + F_2/s \qquad \textbf{(34)}$$

The values of A_1, A_2 etc., and F_1, F_2, etc., are given in Table II. All of the A constants were not used on the final calculation sheet (especially when $x_1 = x_2$) and so those that were used were rearranged and the symbols F_1, F_2, etc., were assigned to those that were used.

Simplification of the Constants

If the primary and secondary reactances be assumed equal, the relations of equations (**19**) to (**22**) apply directly. The values of the various expressions in Table II were determined for $x_1 = x_2$ and are listed in this Table. No approximations have been made and each one of these expressions is exact except the second value given for F_4 and F_7; the first value is exact and it can be seen that each approximation is insignificant.

The procedure to be followed from this point in obtaining the complete performance is amply described in part IV of the paper with the exception of how the slip at maximum torque was obtained, a matter which is developed in the following paragraphs.

Slip at Maximum Torque

The torque developed by a polyphase motor, neglecting friction and windage, is

$$T = \frac{112.6}{\text{syn r.p.m.}} \times \frac{I_2^2 r_2 \times \phi}{s} \qquad \textbf{(35)}$$

$$= \frac{112.6}{\text{syn r.p.m.}} \times \frac{F_7^2 \times r_2 \times \phi}{\left[\left(\frac{F_3}{s} - F_1\right)^2 + \left(\frac{F_2}{s} + F_4\right)^2\right] s}$$

The torque will be a maximum when the expression

$$\left[\left(\frac{F_3}{s} - F_1\right)^2 + \left(\frac{F_2}{s} + F_4\right)^2\right] s$$

is a minimum, a condition which can be found by differentiating the latter and setting equal to zero, whence the slip at maximum torque is found to be

$$s_m = \sqrt{\frac{F_2^2 + F_3^2}{F_1^2 + F_4^2}} \qquad \textbf{(37)}$$

In terms of the fundamental constants of the motor, the above expression becomes

$$s_m = r_2 \sqrt{\frac{1 + \left(\dfrac{r_1 + r_m}{X_0}\right)^2}{\left(X - \dfrac{r_m}{X_0} r_1\right)^2 + \left(r_1 + \dfrac{2}{1+K_p} \times \dfrac{r_m}{X_0} X\right)^2}} \qquad (38)$$

If iron loss be neglected, $r_m = 0$ and (**38**) becomes

$$s_m = \frac{r_2}{\sqrt{r_1^2 + X^2}} \times \sqrt{1 + \left(\frac{r_1}{X_0}\right)^2} \qquad (39)$$

For most practical cases, the quantity under the second radical is so nearly unity that it may be neglected and thus

$$s_m = \frac{r_2}{\sqrt{r_1^2 + X^2}} \text{ (approx.)} \qquad (40)$$

Maximum Torque. The maximum torque in terms of the F constants can be found by substituting equation (**37**) in equation (**36**) obtaining

$$\text{maximum torque} = \frac{112.6}{\text{syn. r.p.m.}}$$

$$\times \frac{F_7^2 \times r_2 \times \phi}{2\left[\sqrt{(F_3^2 + F_2^2)\,(F_1^2 + F_4^2)} + F_2F_4 - F_1F_3\right]} \qquad (41)$$

If the values of the F's in Table II be put into the above expression and r_m be assumed equal to zero, equation (**41**) reduces to

$$\text{maximum torque} = \frac{112.6}{\text{syn. r.p.m.}}$$

$$\times \frac{(EK_p^2)\,\phi}{2\left[\sqrt{r_1^2 + X^2} + K_p^2 r_1\right]} \qquad (42)$$

This latter equation is quite useful in itself for figuring the maximum internal torque of a polyphase induction motor. It is also valuable as a check on the method of Fig. 5 to determine if the F constants are numerically correct.

Discussion

H. R. West: It seems that many designers object to the use of the general method for calculating the performance of a machine as described by Mr. Veinott because it does not enable them to follow the processes with physical interpretation. The answer is, of course, that the purpose of a method of calculation is to enable the designer to predetermine machine performance with the desired accuracy in the least time. Such methods as the circle diagram or the equivalent circuit are, of course, invaluable to anyone who has much to do with motors, but not necessarily for purposes of calculation. That method of calculation should be used which gives the desired accuracy with the least labor, and I believe that the results of algebraic analyses, arranged in systematic form such as Mr. Veinott is using, can profitably be used more than they are at present.

In connection with the correction for the core loss component of primary current in the single-phase motor; Mr. Veinott considers that this component, in calculating the primary copper loss, causes a voltage drop which is not taken into account in figuring the input to the rotor. This means that the calculated motor output is too large by a very slight amount. The error is certainly very small. Has this error been found to be negligibly small in comparison to the error that would be made if the total core loss were subtracted from the output and no correction were made for the primary copper loss?

R. E. Hellmund: Those who designed induction motors many years ago and obtained at that time a rather close agreement between calculations and load tests undoubtedly wonder why new and improved calculating methods such as that presented by Mr. Veinott and others (see bibliography given in paper) should still be an active subject of discussion at Institute meetings. At the same time, it may be a surprise to many to learn that the discrepancy between the results obtained from load tests and those obtained by calculating methods from no-load values and other motor constants has been greater during recent years than it was, say, 20 to 25 years ago. There are no doubt various reasons for this and a brief discussion of a few of them is given in the following.

A comparison of present-day designs and those made about 20 years ago indicates a marked decrease in motor size. This change has taken place gradually, so that many of the effects of it have not been evident at any one time, and, furthermore, they probably have been obscured by various individual changes in the numerous variables entering into the design. Considering, however, that now, as then, the torque of the motor is proportional to the field and the ampere conductors, one cannot escape the conclusion that generally speaking there must be with the smaller dimensions higher flux densities and also more ampere conductors within a unit of space in the up-to-date motors than was found in the older ones; most likely this also means in general more ampere conductors per slot than in the older designs. This means that the zigzag and slot leakage fluxes increase, which will tend toward greater saturation at load, especially in the tooth tips of partially-closed-slot machines; to this must be added the fact that the main flux densities in the same parts have also increased. If we consider now that all theories deriving motor performance from the motor constants neglect the effect of saturation, it is not surprising that in the modern designs there should be a greater discrepancy between such calculated results and tests made under actual load conditions.

Let us, for the sake of argument, assume the extreme case of complete saturation of the tooth tips under load condition by the combined effect of main and leakage fluxes, while at no-load the main flux by itself does not bring about an appreciable saturation of these same parts. Under these assumptions, many of the conditions under load will approach those obtained with an open-slot machine, while at no-load there would be the full benefit of the partially-closed-slot construction. It follows then that the magnetizing current of the main flux under load would be larger, so that the power factor is undoubtedly different from that derived by calculations based on no-load conditions. It follows further that the flux distribution under load in the air-gap will approach that of an open-slot machine and thus cause extra core losses in the surface and in the teeth of both members similar to those that would be obtained if both members were constructed with open slots, and which, as every designer knows, will appreciably differ from those obtained with partially-closed slots. In other words, it is evident that the full-load core losses will be different from the no-load losses which are made the basis of the usual performance calculations. Naturally these extreme assumptions do not exist in actual practise, but it is quite evident that a closer approach to them is generally obtained with the smaller up-to-date motors than with the very much larger motors of the past.

Other changes in design might be cited which would further explain certain differences between the old and the present-day designs. In pointing out these differences, it should not be inferred that this is meant as a criticism of the newer designs. On the contrary, the designers and manufacturers have rendered very valuable service not only by making appreciable reductions in the cost of the motor, but also by greatly reducing the motor dimensions with resultant greater ease of application of motors for all purposes, all of which, of course, is of benefit to the user. This discussion is merely intended to indicate that by the continuous improvement and refinement of motors, the designer has created new problems for himself and perhaps brought about the necessity for a different point of view. Rather than priding himself upon the close agreement between his calculated results and those obtained from actual load tests, he will have to continue the refinement and applicability of his calculating methods such as has been done in Mr. Veinott's paper, as well as of his test methods under load, for the purpose of permitting a more correct determination and analysis of the difference between the two. It is only through such efforts that the effect of changed conditions upon the various constants can be correctly analyzed and so pave the way for still further improvement in motor design.

P. H. Trickey: I have used Mr. Veinott's method for over a year for both single-phase and polyphase motors and for ratings between 2 hp. and 3 watts output, and I have had very satisfactory results.

P. C. Smith: Anyone spending the entire day in the construction of circle diagrams would, no doubt, welcome the easier, faster method presented by Mr. Veinott. The analytical method lacks the visual picture given by the diagram, but it is less tedious, which goes a long way towards off-setting the advantage of the visual picture. The analytical method published by Mr. G. T. Smith in the *Electrical Journal*, December 1922, has been in use since that time on larger polyphase motors, but it was devised particularly for large motors and approximations were made, for simplicity's sake, which make it unsuitable for fractional horsepower sizes. Mr. Veinott's method is more universal, permitting quick approximations or accurate calculations as desired.

The paper goes into great detail in dealing with the current through the shunt circuit, showing the influence of core loss but apparently neglects friction and windage. Do not friction and windage influence this current? The paper also indicates that core loss decreases with the load. This is not always the case.

Item 18 of the polyphase calculation makes use of the secondary resistance in determining the secondary loss. In cases where the actual tested slip is available, it might be advisable to substitute this for the secondary resistance.

C. G. Veinott: Mr. West has raised a question about the relative correctness of the method of correcting the primary current for core loss as presented in this paper with merely subtracting the total core loss from the output. The latter mentioned method assumes all the core loss power to be transferred across the air gap and hence, the power developed by the rotor at full load is slightly too large. The method presented in this paper has been found to give satisfactory results. Indeed, the results are so nearly correct, that it would be difficult to determine if Mr. West's suggestion would be more accurate or not.

Mr. Smith asks whether or not friction and windage influence the current through the shunt circuit. Friction and windage are a mechanical load on the motor and do not influence the current in the shunt circuit.

I am not certain that I understand Mr. Smith's point about secondary resistance. The secondary resistance can be corrected in cases where the actual tested slip is available by multiplying the calculated secondary resistance by the ratio of tested slip to calculated slip. If this is Mr. Smith's idea, it is a very good suggestion.

Measurement of Stray Load Loss
in Polyphase Induction Motors

BY C. J. KOCH*
Associate, A.I.E.E.

Synopsis.—*The purpose of this paper is to present the results of experiments carried out to establish a practical method of measuring stray load loss in induction motors. The nature of stray load losses is discussed, methods of measuring these losses are described, and proposals for the revision of the Institute Standards to include stray load losses are made.*

DEFINITION OF STRAY LOAD LOSSES

As the name indicates, the stray load losses are those losses in addition to the I^2R losses in the motor windings, which occur as a result of the load currents. These losses occur in all types of machines, and their inclusion in efficiency tests on synchronous machines has long been required by the A.I.E.E. Standards.

For d-c. machines, however, only an arbitrary allowance of 1 per cent, and for induction motors no allowance, for these losses is made in the Standards for lack of a satisfactory method of measurement in either case. Were this difficulty removed the desirability of including the stray load losses in efficiency determinations could not be questioned.

The magnitude of stray load losses in polyphase induction motors is not well known at present, but in general it is of the order of from 2 to 5 per cent, in squirrel-cage motors of from 1 to 5 hp. and it decreases gradually with increase in motor rating until it is less than 1 per cent for motors of several hundred horsepower. The "conventional efficiency" of polyphase induction motors as determined by the A.I.E.E. Standards is thus always higher than the actual motor efficiency by the amount of the stray load losses.

This has resulted in awkward situations at times, particularly in the case of motors used to drive apparatus such as pumps or generators. The overall efficiency of the pumping or generating unit being known by measurement and the motor efficiency being determined by the manufacturer on the basis of conventional efficiency, the existence of stray load loss in the motor operates to lower the apparent efficiency of the pump or generator.

Besides removing these inconveniences, the development of any easy method of measuring stray load losses should permit the losses themselves to be studied more intensively and perhaps ultimately to be greatly reduced. The experiments on polyphase induction motor stray load loss determination here described were undertaken with these objects in view.

POSSIBLE SOURCES OF STRAY LOAD LOSS

The losses included in the calculation of conventional efficiency are, primary copper losses as determined by the load current and the measured d-c. resistance of the primary, core loss as determined under running light conditions, friction and windage usually also determined from the running light or excitation tests, and the secondary copper loss determined from the measured slip under load.

These leave as a possible source of stray load loss (a) additional primary copper loss due to eddy currents in the primary conductors, (b) eddy losses induced in the end shields, clamping fingers, etc., by the leakage fields of the primary coil ends, etc., (c) increase in the iron or core loss attendant upon the increase of the stator current from its running-light to its full-load value, and the similar change in the rotor current.

As this paper is principally concerned with stray load losses in moderate size polyphase motors, (c) is the principal item with which we are concerned. Additional losses under item (a) are now so thoroughly understood by designers that they are not permitted to reach large values, and even though corrective measures to reduce them are not undertaken, methods of calculating them are well known and may be relied upon to determine their magnitude. Losses under heading (b) are very difficult to calculate. These losses may be appreciable, especially in high-speed motors where the end leakage reactance is high.

CHANGE OF CORE LOSS WITH LOAD

The running-light core loss of any induction motor is usually several times as large as the "fundamental frequency" loss calculated from the volumes of the stator core and teeth and the magnetic densities existing in these parts. Part of this difference may be due to increased fundamental frequency loss as the result of burrs or punching strains, but the major portion is the tooth-frequency core loss of the motor. It is the tooth frequency core loss which changes with load and forms the principal seat of load loss in moderate size induction motors. The fundamental and tooth-frequency elements of the core loss may be experimentally separated by measurement of the running-light slip of an induction motor.

Although it is difficult to calculate the tooth-frequency core loss in an induction motor under load or for that matter in a motor running light, it is not difficult to show that the tooth-frequency core loss is a function of the load and that its increase with load constitutes a real reason for the observed stray load losses.

---

*General Electric Company, Schenectady, N. Y.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

Consider for example the losses in the rotor surface and teeth of a slip-ring induction motor. These are induced by the stator tooth harmonic flux. This flux may be considered as consisting of two component fluxes, the two component fields having the same number of poles. The first of these is independent of load and is the harmonic flux produced by the action of the fundamental m.m.f. on the stator slot openings. The second varies with load and is due to the tooth harmonic magnetomotive force produced by the concentration of the stator current in slots. It is the increase of this tooth harmonic magnetomotive force with load which accounts for the change of the tooth-frequency core loss with load.

In a squirrel-cage motor, all of the tooth-frequency core loss need not necessarily occur in the laminations. Inasmuch as each rotor tooth of a squirrel-cage motor is embraced by a low-resistance electric circuit, little pulsation of flux can occur in a rotor tooth. Instead, a high-frequency current circulates in the rotor bars and the flux is forced to pulsate in the stator teeth even when the motor is running light. The loss due to this high frequency current in the rotor bars is as much a part of the tooth-frequency core loss of the motor as the eddy and hysteresis losses in the laminations themselves.

Indirect Methods of Measuring Stray Load Loss

All methods of measuring stray load losses may be classified as either direct or indirect. Indirect methods aim to measure the total loss in the motor, subtraction of the conventional losses yielding the stray load loss. Some of these methods are:

a. *The input-output method.* In this method the motor output is measured directly on a dynamometer and the input by wattmeters. The difference is the total motor loss. If it could be carried out accurately the input-output method would of course be the one infallible method of determining stray load loss. Actually in even moderate size motors, both the input and the output have become such large numbers compared to their difference that even a small error in either the one or the other results in very poor accuracy, by the time the necessary subtractions have been made to obtain the stray load loss.

Some of the results presented later in this paper were obtained by the input-output method. The results were obtained with good accuracy only by virtue of the highly developed technique and very accurate equipment, resulting from study and experience in making input-output tests over a period of several years. The equipment was refined to a high degree, the dynamometers being provided with oscillating bearings and the dynamometer errors being accurately determined by running each of three dynamometers against the other two.

b. In order to avoid the necessity of making mechanical measurements of the output an identical motor may be used as a generator, the output then being measured electrically. The load losses are then divided equally between the two machines, after allowing for their different frequencies.

c. *Calorimeter methods.* These consist in measuring the amount of heat carried away from the motor by the cooling air. They are only applicable to large motors and those in which the cooling air is forced to flow in definite passages and even here they yield only fair accuracy.

Other ingenious methods of this nature may be devised such as running the motor in a box with a known amount of air passing through, etc., but these methods are hardly applicable to ordinary shop conditions.

Direct Methods of Measuring Stray Load Loss

Direct methods of measuring stray load loss are based on a procedure by which either the rotor or stator winding is excited with direct current, the unexcited winding being short-circuited. The rotor is revolved at synchronous speed and the amount of power required to do this is measured. This is usually accomplished by coupling the motor to a dynamometer or by driving it from a calibrated direct-current motor. For accurate results, the rating of the driving motor should not be more than 10 per cent of the induction motor rating.

Under these conditions a fundamental frequency current is induced in the conductors of the unexcited member. This current will be of such magnitude that its m.m.f. will very closely equal and oppose the m.m.f. of the direct-current excitation. The only fluxes existing in the motor then are the tooth harmonic fluxes which produce the tooth-pulsation and surface losses the motor experiences under load. In order to find the amount of these losses, it is necessary to subtract from the amount of power required to drive the rotor, the friction and windage loss and also an amount of power equal to the I^2R loss produced by the fundamental frequency current in the unexcited member. The remainder is the surface and tooth-pulsation loss caused by the opposing currents and is approximately equal to the actual stray load loss.

These methods have the advantage that they are usually easy to carry out and the inaccuracies in test are not greatly increased by the subsequent calculations as is the case with the input-output method. Their adaptability to shop conditions makes these methods suitable for approval by the A.I.E.E. if their validity can be established.

Accepting the results of these tests as the true stray load loss of the motor is equivalent to assuming that the tooth-frequency core loss due to the load current m.m.f. may be separately determined as in the direct method, and added to the running-light core loss to obtain the total core loss under load. Whether or not this is a justifiable assumption must be proved experimentally, although it has been found approximately true for synchronous machines. The actual tooth harmonic fluxes which exist in a motor under load are difficult to express analytically and there is little possibility of proving the validity of the direct method by analytical means. Recourse must then be made to comparative tests by direct methods and dynamometer tests. These comparative tests have been made on a number of motors. The results are given in Table I.

TABLE I—LOAD LOSS TESTS

			Direct methods	
	Input-output method	Method *A*	Methods *B* and *C*	Method *D*
Motor No. 1—Full load	306	200	315	
25% overload	498	270	459	
Motor No. 2—Full load	165	87	174	
25% overload	234	145	281	
Motor No. 3—Full load	109	120	122	
25% overload	190	165	197	
Motor No. 4—Full load	321	360	914	
25% overload				
Motor No. 5—Full load	153	100	230	
25% overload	228	160	369	
Motor No. 6—Full load	315		246	
25% overload	505		586	
Motor No. 7—Full load	487		680	500
25% overload	835		1,015	860

25% overload	957		732	
Motor No. 11—Full load			210	146
25% overload			396	287

Direct Methods Applied to Slip-Ring Motors

In making measurements on slip-ring motors, it is customary to excite the rotor with direct current, the stator terminals being short-circuited. An ammeter is included in one of the stator phases. With the rotor revolving at synchronous speed, the rotor excitation is regulated to give a fundamental frequency current in the stator corresponding to the particular load for which the load loss measurement is being made. The amount of loss in the stator winding is then known from the direct current resistance of the stator winding.

It should be noted that when the rotor is excited with direct current, fundamental frequency current flows in the stator windings and the stray load loss which is measured includes, in addition to the tooth pulsation and surface losses, those additional losses mentioned under sources (a) and (b). As these are legitimately a portion of the motor stray load loss, it is preferable, wherever possible, to excite the rotor or secondary winding with direct current rather than the stator. When the stator is excited with direct current the (a) and (b) losses are not present and the indicated stray load loss will on this account be less than actual.

The above method of measuring stray load loss in slip-ring motors will be recognized as nothing more than the accepted method of measuring short-circuit core loss in synchronous motors and generators. A slight difference exists in the case of induction motors, however, and this must be corrected for in testing squirrel-cage motors as well as slip-ring motors.

Direct methods of measuring stray load loss will, of course, give zero load loss for zero stator current. Actually the motor stray load loss is, by definition, zero when the stator current has its running-light or excitation value. This discrepancy may be corrected for by assuming that the exciting current causes a small amount of tooth frequency core loss which is already included in the running-light core loss. The amount of this loss may be found by making measurements with the stator current adjusted to its running-light value. The value of the stray load loss for this value of current being already included in the running-light core loss, should be subtracted from the stray load loss for all other values of current.

Although this method of correcting for the effect of the magnetizing current may not be strictly accurate, the actual amount of the correction is usually small, except for very low-speed motors.

Direct Methods Applied to Squirrel-Cage Motors

In testing squirrel-cage motors, the stator winding is, of course, the only member which can be excited with direct current.

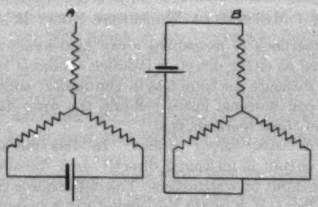

Fig. 1

It is necessary, in order to carry out this method, to determine what value of direct-current excitation corresponds to any particular value of stator load current and also the value of the loss in the rotor due to the fundamental frequency current in the rotor bars. This latter loss must be subtracted from the power required to rotate the rotor or the "rotational watts" in the same way that the stator I^2R loss is subtracted in the case of the slip-ring motor.

The necessary relation between d-c. excitation and r.m.s. load current depends on the way in which the stator terminals are connected. In either case direct-current and alternating-current values are equivalent when they produce the same magnetomotive force in the air-gap. If the connections are as in Fig. 1A

$$I_{\text{D-C.}} = I_{\text{A-C.}} \sqrt{2} \times \frac{\sqrt{3}}{2} = 1.22\, I_{\text{A-C.}} \qquad (1)$$

or if the connections are as in Fig. 1B

$$I_{\text{D-C.}} = I_{\text{A-C.}} \sqrt{2} = 1.414 \text{ A-C.} \qquad (2)$$

It is immaterial which connection is used as long as the proper equation above is used.

In order to determine the loss in the rotor due to the fundamental-frequency current circulating in the rotor bars, four methods are available. Three of these were described in an article by H. E. Linck which was published in the *Archiv fur Elektrotechnik*, Nov. 5, 1929. The methods described in this article seemed promising and furnished one of the incentives for these experiments.

Method A. This makes use of data obtained from a blocked rotor, or impedance test. Simultaneous values of stator current and input watts are taken, with the rotor blocked at standstill and balanced alternating voltages of rated frequency applied to the terminals. If from the input watts under these conditions the stator I^2R loss is subtracted, the remainder is principally the rotor loss. This should be identical with the rotor loss during the stray load loss test if the impedance watts and rotational watts are based on equivalent values of stator current.

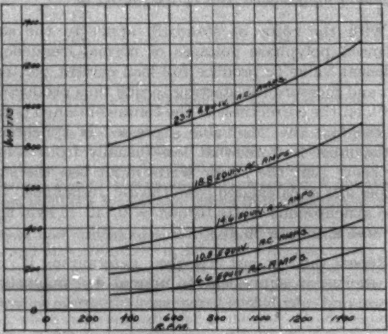

Fig. 2

The rotor loss determined in this way is too large, however, on three accounts. In the first place, if the airgap is small the squirrel-cage currents will not be uniform but will have a tooth harmonic pulsation in their space distribution. The rotor copper loss will thus be larger than that due to the fundamental rotor current which alone determines the full-load slip. Also, since there are actually stator losses of types (a) and (b), and likewise a certain amount of core loss due to the stator leakage flux which exists both under impedance test and under actual load conditions, the rotor loss determined by this method is too large by their amount also. These errors, making the rotor loss too large, make the difference between the total rotational loss and the rotor loss too small. Thus the stray load loss determined in this way is always less than the true stray load loss occurring under short-circuit conditions. As the effect of superposition of load and no-load fluxes is generally to reduce to total loss below the sum of the open- and short-circuit core losses, due to saturation, the error in the loss determination is partially corrected for.

The stator losses of types (a) and (b) and the core losses due to the stator leakage flux above mentioned can be separately determined by repeating the impedance test on the stator with the rotor removed. These losses are usually so small in comparison with the total stray load loss however, that this additional test is not warranted except possibly for very large motors.

This method *A* has an advantage over method *B*, to be described, in that it gives more correct results for double squirrel-cage types of motors.

Method B. This method of determining the rotor loss consists in taking data for a series of curves as shown in Fig. 2. These are curves of rotational watts plotted against speed for various values of stator excitation. For each value of stator excitation the intersection of the rotational watts curve with the axis of zero speed gives the value of rotor I^2R loss.

If the rotor bar resistance varies with frequency an error is introduced and the method becomes useless unless a calculated correction for the change in rotor resistance is made. If this correction is not made this method gives too low a rotor loss and the load loss so determined is correspondingly high. This correction becomes very large when the rotor bars are of the deep bar and double squirrel-cage type.

Since in using this method the stator is excited with direct current, stray load losses of types (a) and (b) will not appear in the result. These are small however, in motors of moderate size.

Method C. This method requires that only one rotational watts curve at synchronous speed be determined by test. The rotor loss is assumed to be equal to the slip loss under load, which is available from the measurements of watts input and slip made when the motor is tested under load. The slip loss should be measured at about 25 per cent overload in order to minimize the effect of the magnetizing current, and the rotor loss is assumed to vary as the square of the exciting current.

It is obvious that the method is practically the equivalent of method *B*, so that the remarks pertaining to double squirrel-cage rotors and losses of types (a) and (b) apply equally here.

The slip loss of the motor under load for any value of stator current is found with sufficient accuracy from the usual formula,

Slip loss = (input — core loss — primary copper loss) slip.

Method D. This, like method *A*, makes use of data obtained from a blocked rotor test. The actual torque developed by the motor at standstill, with balanced alternating voltages of fundamental frequency applied to the stator, is measured by means of a brake arm, or wheel and pulley.

The rotor loss is then equal to the corresponding value of synchronous kilowatts, or to the product of the measured standstill torque in foot pounds by 0.142 times synchronous speed in r.p.m. The value so obtained is less, and more nearly correct, than that given by method *A*, as it does not include the stator losses of types (a) and (b). There is still a slight error due to the net torque produced by the harmonics in the rotor current distribution, but this is normally small.

The standstill torque should preferably be measured at a current of 100 to 150 per cent of the full-load value, and for other loads it may be assumed to vary as the square of the current. The torque at full-load current is normally only 2 to 10 per cent of full-load torque, or it is of the same order as the static friction torque. For this reason, very careful torque readings with the rotor turned both with and against the torque must be taken to average out the friction and the irregularities of the torque position curve.

RESULTS

A summary of the results of measurements of the stray load loss of a number of induction motors using both input-output and direct methods is contained in Table I.

A review of these results indicates that for squirrel-cage motors the best results are obtained using method *C*, or preferably method *D*. Method *C* is easily carried out, and gives accurate results for all small motors which have no appreciable eddy current effect in the rotor bars at starting. When double squirrel-cage rotors are used the method is inaccurate. Motor No. 4 was built with a double squirrel-cage rotor.

Using method *D*, the only error in the determination of the true stray load loss is the omission of the stator losses of types (a) and (b). This error is normally small and may be balanced by the consideration that the stray load loss under actual load conditions is probably somewhat less than that at short circuit because of saturation.

For slip-ring motors the most satisfactory method appears to be to measure the rotational loss with the rotor excited with direct current and to subtract the stator I^2R loss as determined from the measured stator current and the d-c. resistance.

Detailed outlines of these preferred tests are given in Appendix A. It is proposed that after confirmation or modification by other investigators, these methods be taken as the basis for a revision of the Institute Standards to require the inclusion of induction motor stray load losses in efficiency determinations.

Appendix A

PROPOSED METHOD OF DETERMINING STRAY LOAD LOSS IN INDUCTION MOTORS

Slip-Ring Motors

1. Measure the power required to drive the motor at synchronous speed with the primary winding short-circuited and sufficient d-c. excitation applied to the secondary winding to cause full-load current to circulate in the primary; the power required is designated W. From the d-c. resistance (making any corrections necessary for differences in temperature) determine the primary I^2R loss and designate this as T.

2. Repeat the test just outlined with the primary current equal to the magnetizing current; and determine the rotational power required and the I^2R loss; these latter are designated W_o and T_o.

3. The stray load loss is then equal to $W-W_o-T+T_o$.

Squirrel Cage Motors

1. Apply d-c. excitation to the stator using two of the stator terminals and leaving the third open; the amount of direct-current required is 1.22 times the full-load alternating-current per terminal. Under these conditions determine the power required to rotate the rotor at synchronous speed; this is designated W.

2. With the rotor at standstill apply to the stator balanced polyphase voltages of normal frequency of sufficient value to produce full-load current per terminal, and measure the starting torque thus produced. A check on the correctness of the torque obtained is given by the fact that its value expressed in synchronous watts, must be somewhat less (usually from 5 to 20 per cent) that the stator watts input less the stator copper loss as calculated from the d-c. resistance. Then T = synchronous watts torque = 0.142 × syn. speed (r.p.m.) × torque (lb. ft.).

3. Repeat the test just described, determining W_o with d-c. excitation equivalent to normal a-c. magnetizing current and calculate

$$T_o = T_s\left(\frac{\text{Magnetizing current}}{\text{Full-load current}}\right)^2$$

4. The stray load loss is then $W - W_o - T + T_o$.

In practise, the starting torque varies closely as the square of the primary current; it is desirable therefore to measure the value of T at only one value of current, selected to obtain the greatest accuracy of test, and to obtain the values of T at other points by proportionality. The best value of current to select for this test will depend somewhat upon the type and size of motor. If the current is too large, overheating takes place and errors arise due to incorrect conductor temperature determinations. On the other hand, if too low values of current are used, the small torque produced in comparison with the static friction makes it difficult to obtain accurate values. It is recommended that full-load current normally be used for squirrel-cage and ball-bearing motors, while values of 150 per cent full load current are recommended for normal use on sleeve-bearing motors of less than 25 hp.

Discussion

Orrin C. Rutledge: Since Mr. Koch's tests were made on machines of different sizes and types a more comparative idea of the results can be obtained by placing them on a percentage basis. Taking the values in Table I obtained by input-output method as 100 per cent in each case we obtain the following figures for the direct methods.

Method	% Load	Number of machines	Average	Minimum	Maximum
A	100	8	68.2%	31.4%	112.2%
	125	6	63.5	46.4	86.8
B and *C*	100	9	110.4	78.1	150.5
	125	9	112.6	76.5	161.0
D	100	1	103.0		
	125	1	103.0		

Method *A* gives low values and Mr. Koch has explained the reason for this.

Method *D* is the one proposed by Mr. Koch for adoptions in the standards but from Table I it is only possible to compare this with the input-output method on one machine.

Methods *B* and *C* give permissable average values but as may be seen there is a considerable spread from minimum to maximum.

I have been making some tests on a 10-hp. wound rotor machine and have endeavored to determine stray load loss by both input-output and direct methods, computing copper losses by d-c. resistance and measured currents in all cases. Plotting loss against line current the input-output method gives the curve (1) Fig. 1, which varies approximately as the cube of load component of line current.

The direct method gives approximately the same results whether the excitation is placed on rotor or stator, using either connection *A* or *B* in Mr. Koch's Fig. 1. This is shown in this discussion as curve 2, Fig. 1. It will be noted that the curve passes through the origin and has a value of about 60 watts when the equivalent current has a value equal to the no-load magnetizing current. It is considered that this value corresponds to the no-load pulsation loss but another test, proposed by Mr. Alger in 1920, showed a no-load pulsation loss of about twice this value.

If this is a true value of no-load pulsation loss it should be subtracted from all subsequent points moving the curve vertically downward into the position shown as curve 3, since by definition there is no "load loss" at no-load.

I would suggest consideration of the possibility that the a-c. equivalent of the d-c. current is comparable to the load component of line current under normal operation rather than the total line current. In that case we would add exciting component vectorially for each point to get it in terms of line current. This would have the effect of moving the curve nearly horizontally to the right instead of vertically downward, and of increasing the slope somewhat, (see curve 4).

The same process would be applied to Mr. Koch's method *D* for determining copper loss of the unexcited member. This loss would then also be zero when the line current equals the exciting current rather than when the line current is zero.

The curves indicate that in the vicinity of full load the loss by direct measurement is of the same order of magnitude as that by input-output determination. This checks with Mr. Koch's results. However, the shape of the curve would still leave open the question as to whether or not the pulsation loss by the d-c. method is a correct representation of the true pulsation loss occurring under load.

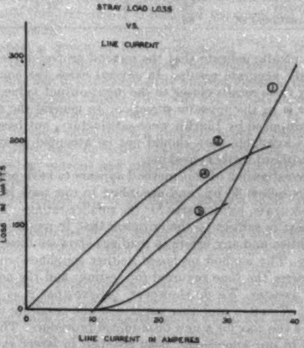

FIG. 1

O. C. Schoenfeld and S. F. Henderson: We have been studying the subject of stray load losses with the object of determining their value in our designs and are glad that it has been brought up for discussion. We, also, have been testing motors by the input-output method for a considerable period, but found, as did Mr. Koch, that many refinements were necessary to obtain results of the degree of accuracy desired for a study of the stray load losses.

The method outlined by Mr. Koch has some merits, but it must be admitted that it is not theoretically correct, nor could we check it experimentally. We believe that proper consideration has not been given to the effect of saturation. This factor alone can have considerable influence and as a result the d-c. short-circuit method gives values of losses in excess of those obtained under normal load conditions. A theoretical discussion as well as an experimental check of this method and the effect of saturation is given in an article by L. Dreyfuss in the July 7, 1928 issue of *Archiv für Elektrotechnik.* Making use of a paper entitled "Iron Losses for Simultaneous Magnetization at Two Different Frequencies" written by F. Schroeter and published in the 1924 issue of the same magazine, Linckh, in the article mentioned by Mr. Koch, explains this influence and proves it experimentally by tests on a series of 10 motors. The tests which we made check the observations of these authors.

Linckh found that correction factors were necessary and states, "It is probable that for practical purposes the accuracy of the constants is sufficient. However, the values have been found by readings on a comparatively small number of motors and it should be desirable that others should make similar investigations, especially on machines of larger ratings." The correction factors proposed are

$$\text{slip-ring motors } 0.5\ \frac{I^2 - I_0^2}{I^2}$$

$$\text{squirrel-cage motors } \frac{I^2 - I_0^2}{I^2 DC}$$

where the currents are stator currents. The method is, otherwise, essentially the same as that proposed by Mr. Koch and it will be noted that the corrections are of such magnitude that they cannot be neglected.

The following is a brief tabulation of our tests.

Full load efficiencies and stray load losses

Motor No.	Brake values	Linckh		Koch		
		B	C	B	C	D
1 Stray loss watts	115.0	140.0	165.0	225.0	265.0	431.0
% Efficiency	86.5	86.1	85.7	85.0	84.4	82.4
% Conventional eff.	88.4					
2 Stray loss watts	140.0	216.0		347.0		
% Efficiency	86.5	85.3		83.8		
% Conventional eff	88.7					
3 Stray loss watts	402.0	410.0		643.0		
% Efficiency	82.3	82.2		79.5		
% Conventional eff	88.6					
4 Stray loss in watts	157.0	170.0		270.0		372.0
% Efficiency	85.9	85.5		84.3		83.0
% Conventional eff	88.3					
5 Stray loss in watts	87.0	77.0		130.0		220.0
% Efficiency	86.2	86.4		85.3		83.6
% Conventional eff	88.3					
6 Stray loss watts	112.0	145.0		225.0		362.0
% Efficiency	86.2	85.8		84.8		83.0
% Conventional eff	88.1					

These results indicate that the method proposed does not give sufficiently accurate results. In several cases the conventional efficiency gave results closer to the input-output value, although the error is in the opposite direction. In general the correction factors proposed by Linckh were satisfactory, but based on the few tests available they should not be accepted as sufficiently correct without further checking.

The investigation of this method appears to have been limited to ratings below 30 hp. and according to our tests is not sufficiently accurate, particularly for the smaller ratings. The input-output test is subject to the criticism that it requires accurate test facilities and any errors in readings show up directly in the efficiency. The method proposed neither simplifies the facilities nor shortens the time required for testing, and the accuracy is not any greater. We do, however, believe that it is a step in the right direction and this paper and the resulting discussion may pave the way for a new or modified procedure. The method has not, to our knowledge, been checked in larger ratings and it may prove to be sufficiently accurate in this range where a dynamometer is not available. This can be determined only by experimental tests, and it appears that further investigation is warranted.

L. E. Hildebrand: The present conventional efficiency ignoring load loss does not give correct efficiency.

The theoretically correct input-output test requires a highly trained crew, highly developed equipment and highly developed technique to obtain satisfactory results and even then, it is expensive and subject to question.

In all practical work a conventional efficiency test *including* a conventional load loss is certainly superior to ignoring load loss. Also in the hands of an average crew with average equipment it should be superior to the impractical input-output test providing a method is used for determining a conventional load loss which gives consistently repeatable results approximately equal to the true load loss. We may as well face the fact that there has been developed no method for accurately determining the real load loss. A conventionally determined load loss should average close to the true load loss if proper account is taken of the factors which might vitiate the results.

Mr. Koch has pointed out those connected with the determination of the subtractable true secondary I^2R loss. His method for slip-ring motors is certainly essentially sound. His methods *B*, *C* and *D* all seem equally sound for single-cage motors and *C* is more convenient than *B*, so we should use either *C* or *D*. *C* is unsound for double cage and other rotors with deep bar effect. His method *D* would seem the best in general if it were not for two factors, first, the determination of the true starting torque at full load current and operating temperature is not quite as simple as it sounds due to the friction and heating factors. Second, method *C* sometimes gives closer to the true facts with single-cage motors.

It would seem that a method for determining a conventional efficiency including a conventional load loss should be legalized. Mr. Koch's proposed method *D* (with *C* as a permissible alternative for single-cage motors) seems practical for a tentative permitted method.

H. L. Barnholdt: The subject treated in Mr. Koch's paper is a very timely one and a satisfactory solution to this difficult problem is much to be desired.

That the problem of directly measuring stray load losses in induction motors is a difficult one is evidenced by the wide discrepancies shown by the test results. For squirrel-cage induction motors it is stated that method *D* is preferred, but only one test is indicated comparing it with the input-output test and while this checks quite closely, it is entirely possible that if a number of tests was made according to method *D* they would show as wide discrepancies as methods *A*, *B*, and *C*. Since the several methods admittedly are based on experimental data only, it is believed that further tests and greater consistency of test results are necessary before attempting standardization.

The method proposed for squirrel-cage motors does not take into account additional primary copper losses due to eddy currents in the primary conductors or the eddy losses induced in the end shields, etc., by the leakage fields of the primary coil ends, although the latter is admitted to be appreciable, especially in high-speed motors. Hence, even after making all these tests, the validity of the test results would still be open to question by the pump builders, particularly since high-speed squirrel-cage motors are used mainly by them.

For these reasons, it would probably be better, on smaller motors, to determine the efficiency by the input-output dynamometer method which, if properly carried out, could not be open to question. This would take care of the bulk of the motor production and would cover the class of machines where the stray load losses are the greatest.

In the case of larger induction motors, it is known that the stray load losses are relatively of less importance than on smaller machines. For example, some years ago the writer had occasion to make input-output efficiency tests of two 7,000-hp. induction motors and the efficiency by this method checked to within one-quarter of one per cent with the efficiency computed from the separate losses determined in the usual manner. Since it is impracticable to apply the dynamometer test regularly to larger motors and since here the stray load losses are relatively small, an arbitrary allowance say ¾ per cent could be made to cover stray load losses on large induction motors. Input-output tests could be made as opportunities presented themselves, with the idea of revising the allowance as soon as more test data would become available. This would have the advantage of simplicity, would inflict no hardship on anyone and would probably give results fully as accurate as those obtained by the proposed method.

C. G. Veinott: Mr. Koch is to be highly commended for his endeavor to measure the stray load loss in polyphase induction motors, however inaccurate his method may be. That such losses do actually exist there can be no doubt and it is essential for the designer to have some idea of their magnitude before they can be successfully reduced.

Suppose that the stray load losses were known, how would Mr. Koch suggest account be taken of these in calculating the performance of the motor by the equivalent circuit?

Mr. Koch recommends that either his method or some other method for determining stray load losses be added to A.I.E.E. "conventional" efficiency calculations. At present the Institute recognizes directly measured efficiency and conventional efficiency but rule 9-302 states that "Unless otherwise specified the conventional efficiency shall be employed." The Institute thus makes no distinction between large and small motors. I think Mr. Koch's paper brings out reasons why the Institute should make a distinction between large and small motors and should, in my opinion, recommend the directly measured efficiency (input-output) for the latter. This opinion is stated on the grounds that, for small motors, stray load losses are most important, the input-output method is easier, cheaper and more reliable to make. Just where the dividing line should be put is perhaps doubtful, but it certainly should be above 3 hp.

P. L. Alger: It is very desirable to establish a standard method for determining induction motor load losses, and while Mr. Koch's proposals are fundamentally sound, there is much to be done in the way of study and tests before any method can be adopted as a standard.

Measurement of the rotational losses by driving the motor at normal speed with direct current in the stator winding is an essential element in any direct measurement of stray load loss. A difficulty arises, however, in the determination of the correct secondary I^2R loss to be subtracted from the total rotational losses. If the rotor I^2R loss is determined on the basis of the resistance corresponding to normal load slip, the value obtained is too small, since it does not include the full frequency rotor iron and copper losses. These errors are very large on deep bar or double squirrel-cage motors, and for this reason methods *B* and *C* are regarded as undesirable for general use.

While determination of the rotor losses by measurement of the standstill torque at full load current gives theoretically almost correct results, it is very difficult to carry out in practise on small motors, because of the irregularity of the torque position curve and the errors due to bearing friction.

Determination of the rotor losses by measuring the impedance watts input and subtracting from it the primary I^2R loss is convenient and approximately correct in the case of overhung slot motors, but it gives a value of rotor loss which is slightly too large, and therefore gives a value of stray load loss somewhat too small. This error is somewhat offset by the existence of saturation in the flux leakage paths under normal load conditions. It seems practical, therefore, to get accurate results by this method, if a simple correction factor of perhaps 10 per cent is applied to the primary copper loss, to be subtracted from the impedance watts input.

In conclusion method *A* should form the basis of standards for stray load loss measurement in the case of overhung primary slot motors of 1 hp. and larger, with the addition of a multiplying factor of perhaps 1.1 for the primary copper loss on the standstill impedance test.

Method *D* should form the basis of standards for stray load loss measurement in the case of open primary slot motors (which are generally built in ratings of 20 hp. and larger).

Direct input-output tests should remain standard for fractional hp. motors and should remain optional for larger motors.

The Induction Motor Subcommittee of the Committee on Electrical Machinery is now reviewing this problem, and plans to submit some definite recommendations on the subject to the Standards Committee in the near future.

C. J. Koch: We are fortunate in having discussion contributed by gentlemen who have had the opportunity to test in their factories the procedures described in this paper. The result of their experiences leaves in doubt the desirability of adopting the proposals of this paper at least for motors of moderate size. It is perhaps true that for motors below 50 hp. a direct input-output test on a dynamometer will give the true efficiency with sufficient accuracy and with less expense than the no-load test required to find the conventional efficiency and the separate determination of the stray load loss. For large motors the dynamometer is quite impracticable however and it is believed the proposed methods will be of real value.

A few specific questions have been asked. It is true that using any of the proposed methods for squirrel-cage motors, stray load loss due to additional eddy current losses in the stator conductors, clamping fingers, etc., will not be included as the stator is excited with direct current. These losses in modern designs are usually small but if a question arises regarding their magnitude they may be easily checked by exciting the stator with alternating current and measuring the watts loss with the rotor removed.

There is no simple way of including the stray load loss in the equivalent circuit. For any value of load it should be subtracted from the gross output of the motor along with the friction and windage losses. This is based on the assumption that the stray load loss is all increase in tooth frequency core loss. (See Alger and Eksergian.) This procedure although correct would not be really an inclusion of the stray load loss in the equivalent circuit as for other loads the equivalent circuit would not tell the magnitude of the stray load loss. This would be found by other means.

Torque-Angle Characteristics of Synchronous Machines Following System Disturbances

BY S. B. CRARY*
Associate, A.I.E.E.
and
M. L. WARING*
Associate, A.I.E.E.

***Synopsis.**—A method of predetermining the torque-angle characteristic of a synchronous machine following a system disturbance is of importance in calculating the transient stability limit and in evaluating the effect on this limit of additional rotor circuits or of a change in excitation. In the first part of this paper equations are derived which are of sufficient generality to evaluate such factors. Two types of system disturbances are considered:*

1. Switching in or out of a connecting line,

2. Occurrence of a balanced three-phase system fault.

In the second part, an actual case of switching out a connecting line is calculated and the results compared with field tests taken on the New York Power and Light Corporation's system.

No attempt has been made to draw any general conclusions as to the effect of amortisseurs or changes in excitation. A subsequent paper will present results which have been obtained from the application of the method presented in this paper.

INTRODUCTION

THE determination of the behavior of synchronous machines during transient conditions subsequent to a system disturbance is becoming increasingly interesting and important. In determining this behavior it is essential to know the torque-angle characteristic of the given machine under conditions resulting from disturbances of various sorts. The most important of such disturbances are variations in (1) mechanical torque, (2) excitation voltage, (3) amount of external reactance, (4) system voltage. System voltage may vary either in magnitude or in angular position.

The cases of cyclic variation of impressed torque, sudden angular displacement and synchronizing out of phase have already been treated by Doherty and Nickle.[4] Equations for the damping and synchronizing components of pulsating torque caused by a given small angular pulsation of the rotor for any number of rotor circuits have been derived by Park.[2]

A problem of particular interest to operators is that of the variation in torque caused by a change in external reactance due either to the switching in or out of a line, or due to the occurrence of a system fault. This problem has been discussed in some detail by various authors[5,6,7,8] under the subject of system stability. The purpose of this paper is to establish general equations from which may be derived specific equations applying to any of the particular conditions mentioned above. Starting with the fundamental relations developed by Park,[2] general equations are derived for the positive phase sequence torque of a synchronous machine subsequent to the following system disturbances:

1. Switching in or out of a connecting line.
2. Occurrence of a balanced three-phase system fault.

The evaluation of the torque characteristics following such disturbances is of particular importance in the determination of transient stability limits. A step-by-step method of calculation is given so that the electrical torque of a machine having any number of rotor circuits can be determined at any time of its swing. The formulas and step-by-step method presented make it possible to predetermine such phenomena as that produced by amortisseur windings, high-speed excitation, etc.

ASSUMPTIONS

In order to simplify the mathematical work and to permit the use of operational solutions certain assumptions which appear to be reasonable and practical have been made. These are:

1. The machine is connected to a relatively large system; *i. e.*, it is assumed that the machine terminals are connected to an infinite bus through external impedance.
2. The machine is ideal as defined in reference 1.
3. Armature and line resistance are negligible.
4. The effect of the direct-current components of transient armature current, and all induced currents resulting therefrom, may be neglected in computing the torque.
5. The component of transient armature voltage due directly to the rate of change of magnitude of the rotor flux may be neglected in comparison with the voltage due to the rotation of this flux with respect to the armature. This assumption is justifiable for all ordinary machines.
6. The variations in rotor speed due to its oscillation with respect to the connected system may be neglected in the calculation of induced voltages.

I—Mathematical Analysis

FUNDAMENTAL RELATIONS

Using the two-reaction method of analysis it is possible to determine the characteristics of a synchronous machine from a consideration of two circuits. One of these, the direct axis circuit, represents those circuits which are symmetrical about the axis of the poles and the other, the quadrature axis circuit, represents those circuits which are symmetrical about the axis between the poles.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

The fundamental relations upon which are based the equations developed in this paper were derived by Park[3] and are as follows:

$$\left.\begin{aligned}\Psi_d &= G(p)E - x_d(p)i_d \\ \Psi_q &= -\,x_q(p)i_q\end{aligned}\right\} \qquad (1)$$

$$T = i_q\Psi_d - i_d\Psi_q \qquad (2)$$

$$\left.\begin{aligned}i_{do} &= \frac{E_{do} - \Psi_{do}}{x_d} \\ i_{qo} &= -\,\frac{\Psi_{qo}}{x_q}\end{aligned}\right\} \qquad (3)$$

$$\left.\begin{aligned}\Psi_d &= e\cos\delta \\ \Psi_q &= -\,e\sin\delta\end{aligned}\right\} \qquad (4)$$

$$\left.\begin{aligned}e_d &= p\Psi_d - ri_d - \Psi_q p\theta \\ e_q &= p\Psi_q - ri_q + \Psi_d p\theta\end{aligned}\right\} \qquad (5)$$

The operational impedance of the direct-axis circuit met by the current resulting from a unit function change of terminal linkages in the direct axis is called $x_d(p)$. Similarly $x_q(p)$ is the operational impedance of the quadrature axis circuit. $G(p)$ is an operator which relates the field voltage with the current and linkages in the direct axis. A method of deriving these operators from the equivalent circuits of the direct and quadrature axes has been presented.[13]

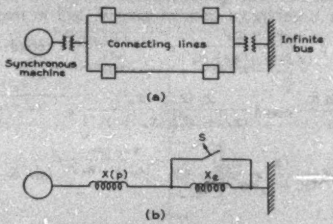

FIG. 1—SYSTEM DIAGRAM AND EQUIVALENT CIRCUIT FOR SWITCHING OPERATION

Case 1. Switching Out a Connecting Line

Consider the case of a synchronous machine connected to a very large system through two or more parallel transmission lines as shown in Fig. 1a. The machine is operating with a steady excitation voltage E_{do} and displacement angle δ_o before $t = 0$. If, at the instant $t = 0$, one of the lines is suddenly opened, there will be an instantaneous change in the amount of reactance between the machine and the infinite bus. An equivalent circuit representing this condition is shown in Fig. 1b where a reactance x_e is suddenly inserted by opening the switch S; $x(p)$ represents $x_d(p)$ for the direct and $x_q(p)$ for the quadrature axes; $x(p)$ includes the machine reactance plus the external reactance between the machine terminals and the infinite bus before the switch S is opened.

The effect of opening a switch which is carrying a current i' may be simulated by leaving the switch closed and impressing a current equal and opposite to i' through it so that by the superposition of the two, the resultant current through the switch is zero. Since no current was flowing through x_e before opening the switch the component of the impressed current which flows through x_e is the resultant current flowing between the machine and the infinite bus. We have, then:

$$i = \frac{x(p)}{x_e + x(p)}\,i' \qquad (6)$$

where

i = the value of current after opening the switch

and

i' = the value of current that would flow through the switch S if it were not opened.

The components of i' are:

$$\begin{aligned}i_d' &= i_{do} + \Delta i_d \\ i_q' &= i_{qo} + \Delta i_q\end{aligned} \qquad (7)$$

where from equation (1):

$$\begin{aligned}\Delta i_d &= -\,\frac{1}{x_d(p)}\,\Delta\Psi_d + \frac{G(p)}{x_d(p)}\,\Delta E \\ \Delta i_q &= -\,\frac{1}{x_q(p)}\,\Delta\Psi_q\end{aligned} \qquad (8)$$

Substituting equations (3) and (8) in equations (7):

$$\begin{aligned}i_d' &= \frac{E_{do} - \Psi_{do}}{x_d} - \frac{1}{x_d(p)}\,\Delta\Psi_d + \frac{G(p)}{x_d(p)}\,\Delta E \\ i_q' &= -\,\frac{\Psi_{qo}}{x_q} - \frac{1}{x_q(p)}\,\Delta\Psi_q\end{aligned} \qquad (9)$$

Equations (9) may now be substituted in equation (6) giving the direct and quadrature components of transient current of the machine subsequent to the switching operation. After re-arrangement and substitution of equations (4) in (9):

$$\begin{aligned}i_d &= \frac{E_{do} - e\cos\delta_o}{x_d}\;\frac{x_d(p)}{x_e + x_d(p)} \\ &\quad - \frac{e}{x_e + x_d(p)}\,(\cos\delta - \cos\delta_o) + \frac{G(p)}{x_e + x_d(p)}\,\Delta E \qquad (10) \\ i_q &= \frac{e\sin\delta_o}{x_q}\;\frac{x_q(p)}{x_e + x_q(p)} + \frac{e}{x_e + x_q(p)}\,(\sin\delta - \sin\delta_o)\end{aligned}$$

The operators contained in equations (10) may be expanded by Heaviside's expansion theorem when operating on a unit function. However, the second terms of both equations contain an operator which is operating on a function of the machine angle which may vary with time. If the relationship between the angle and time is known it would be a simple matter to expand the expression by means of Duhamel's integral. However, since this relation is not generally known it is usually necessary to obtain the solution by means of a step-by-step calculation.

One form of Heaviside's expansion theorem is:

$$\frac{Y(p)}{Z(p)} = \frac{Y(o)}{Z(o)} + \left[\frac{Y(\infty)}{Z(\infty)} - \frac{Y(o)}{Z(o)} \right] \sum a_n \epsilon^{p_n t} \tag{11}$$

where

$$a_n = \frac{Z(\infty)Z(o)}{Y(\infty)Z(o) - Z(\infty)Y(o)} \cdot \frac{Y(p_n)}{p_n Z'(p_n)}$$

p_n = root of equation $[Z(p) = 0]$

and $\Sigma a_n = 1.0$.

Applying this theorem to the operators in equations (10):

$$\begin{aligned} i_d = {} & \frac{E_{do}}{x_e + x_d} - \frac{e \cos \delta}{x_e + x_d} - \frac{E_{do} - e \cos \delta_o}{x_d} \\ & \cdot \frac{x_e (x_d - x_d'')}{(x_e + x_d)(x_e + x_d'')} \sum a_{dn} \epsilon^{-\alpha_{dn} t} \\ & - \frac{e (x_d - x_d'')}{(x_e + x_d)(x_e + x_d'')} \sum b_{dn} \epsilon^{-\alpha_{dn} t} (\cos \delta - \cos \delta_o) \\ & + \frac{G(p)}{x_e + x_d(p)} \Delta E_d \\ i_q = {} & \frac{e \sin \delta}{x_e + x_q} - \frac{e \sin \delta_o}{x_q} \cdot \frac{x_e (x_q - x_q'')}{(x_e + x_q)(x_e + x_q'')} \sum a_{qn} \epsilon^{-\alpha_{qn} t} \\ & + \frac{e (x_q - x_q'')}{(x_e + x_q)(x_e + x_q'')} \sum b_{qn} \epsilon^{-\alpha_{qn} t} (\sin \delta - \sin \delta_o) \end{aligned} \tag{12}$$

Substitution of equations (4) and (12) in equation (2) gives:

$$\begin{aligned} T = {} & \frac{E_d e \sin \delta}{x_e + x_d} + e^2 \frac{x_d - x_q}{2 (x_e + x_d)(x_e + x_q)} \sin 2 \delta \\ & - \frac{E_{do} e - e^2 \cos \delta_o}{x_d} \sin \delta \frac{x_e (x_d - x_d'')}{(x_e + x_d)(x_e + x_d'')} \sum a_{dn} \epsilon^{-\alpha_{dn} t} \\ & - e^2 \sin \delta \frac{x_d - x_d''}{(x_e + x_d)(x_e + x_d'')} \sum b_{dn} \epsilon^{-\alpha_{dn} t} (\cos \delta - \cos \delta_o) \\ & - \frac{e^2 \sin \delta_o}{x_q} \cos \delta \frac{x_e (x_q - x_q'')}{(x_e + x_q)(x_e + x_q'')} \sum a_{qn} \epsilon^{-\alpha_{qn} t} \\ & + e^2 \cos \delta \frac{(x_q - x_q'')}{(x_e + x_q)(x_e + x_q'')} \sum b_{qn} \epsilon^{-\alpha_{qn} t} (\sin \delta - \sin \delta_o) \\ & - \frac{e \sin \delta}{x_e + x_d} \sum c_{dn} \epsilon^{-\alpha_{dn} t} \Delta E \end{aligned} \tag{13}$$

The above expression is the equation for the torque developed by a synchronous machine when an external reactance is suddenly switched in, accompanied by a change in angle from δ_o to δ and a change of excitation voltage ΔE. This expression for torque is general, within the limitations of the original assumptions, in that it includes the effect of any number of rotor circuits as well as any change in excitation voltage.

If the variations of δ and E as functions of time are known, Duhamel's integral may be applied and the electrical torque determined directly at any time after the disturbance. However, if they are not known, as is the more usual case, the step-by-step method of calculation presented in Appendix A may be used to determine the angular swing of the machine.

For one rotor circuit in each axis equation (13) becomes:

$$\begin{aligned} T = {} & \frac{E_d e}{x_e + x_d} \sin \delta + e^2 \frac{x_d - x_q}{2 (x_e + x_d)(x_e + x_q)} \sin 2 \delta \\ & - \frac{E_{do} e - e^2 \cos \delta_o}{x_d} \sin \delta \frac{x_e (x_d - x_d')}{(x_e + x_d)(x_e + x_d')} \epsilon^{-\frac{x_d + x_e}{(x_d' + x_e) T_{do}'} t} \\ & - e^2 \sin \delta \frac{x_d - x_d'}{(x_e + x_d)(x_e + x_d')} \epsilon^{-\frac{x_d + x_e}{(x_d' + x_e) T_{do}'} t} (\cos \delta - \cos \delta_o) \\ & - \frac{e^2 \sin \delta_o}{x_q} \cos \delta \frac{x_e (x_q - x_q')}{(x_e + x_q)(x_e + x_q')} \epsilon^{-\frac{x_q + x_e}{(x_q' + x_e) T_{qo}'} t} \\ & + e^2 \cos \delta \frac{(x_q - x_q')}{(x_e + x_q)(x_e + x_q')} \epsilon^{-\frac{x_q + x_e}{(x_q' + x_e) T_{qo}'} t} (\sin \delta - \sin \delta_o) \end{aligned} \tag{14}$$

Case 1a. Constant Flux Linkages Maintained in Both Axes

In order to simplify calculations the approximations are frequently made that constant flux linkages are maintained in the predominant rotor circuit of each axis at any instant after the occurence of the disturbance and that the effect of additional rotor circuits is negligible. Such an assumption simply specifies that the predominant rotor circuit of each axis has an infinite time constant whereas all additional rotor circuits in both axes have zero time constants.

If such an assumption is made equation (13) may be greatly simplified as all of the exponentials will become either unity or zero depending upon whether the time constant of the particular circuit it represents is infinite or zero. Also $x_d'' = x_d'$; $x_q'' = x_q'$. Equation (13) becomes:

$$\begin{aligned} T = {} & \frac{x_d' E_{do} e}{x_d (x_d' + x_e)} \sin \delta + \frac{e^2 (x_d' - x_q')}{2 (x_d' + x_c)(x_q' + x_e)} \sin 2 \delta \\ & + \frac{e^2 (x_d - x_d')}{x_d (x_d' + x_e)} \cos \delta_o \sin \delta - \frac{e^2 (x_q - x_q')}{x_q (x_q' + x_e)} \sin \delta_o \cos \delta \end{aligned} \tag{15}$$

If x_e is zero equation (**15**) corresponds to equation (**46**) of reference 4 for sudden angular displacement. Also, making $x_e = 0$, $E_{do} = e$ and $\delta_o = 0$, (the last two relations being the conditions for a machine initially open-circuited) equation (**15**) reduces to equation (**61**) of reference 4 for synchronizing out of phase.

In making stability studies involving several machines the assumptions are commonly made that $x_d' = x_q'$ and $x_d = x_q$. Equation (**15**) becomes:

$$T = \frac{x_d' E_{do} e}{x_d (x_d' + x_e)} \sin \delta + \frac{e^2 (x_d - x_d')}{x_d (x_d' + x_e)} \sin (\delta - \delta_o) \qquad (\mathbf{16})$$

By trigonometric transformations equation (**16**) may be readily shown to be equal to the more common form:

$$T = \frac{E' e}{x_d' + x_e} \sin \delta' \qquad (\mathbf{17})$$

Where E' = the voltage back of transient reactance.
δ' = the angle between E' and e.

Case 1b. Switching in a Connecting Line

If a connecting line is switched in, the equivalent one line circuit of Fig. 1b may be used by giving x_e a negative value. The above equations may therefore be applied for switching in a connecting line, as well as for switching out a connecting line, providing x_e is given the proper sign.

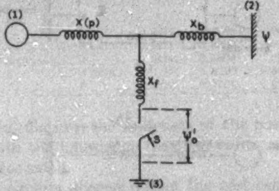

Fig. 2—Equivalent Circuit Representing Occurrence of Balanced Fault

Case 2. Occurrence of a Balanced Three-Phase System Fault

The calculation of the transient stability limit frequently involves the determination of the relation between torque, machine angle and excitation following the occurrence of a balanced three-phase system fault. Faults on a system connecting one machine and an infinite bus can be reduced to an equivalent circuit of the form shown in Fig. 2. The occurrence of the fault is represented by closing the switch, S. $x(p)$ is the machine reactance plus the reactance of that part of the equivalent Y-circuit which extends from the machine terminals to the junction point of the Y.

In keeping with assumptions 3, 4, 5, and 6, equations (**5**) reduce to the following simple relations:

$$e_d = -\Psi_q$$
$$e_q = \Psi_d$$

Switching operations may then be made by suddenly applying flux linkages equal in magnitude to the corresponding voltages. In the network of Fig. 2, the effect of closing the switch may, therefore, be simulated by leaving it open and, at the instant $t = 0$, impressing across it a value of flux linkages, Ψ_o', equal and opposite to the value that existed before $t = 0$. At $t = 0$, δ and E may also change, depending upon the conditions of the problem.

Before $t = 0$, the current flowing through x_b to the infinite bus is

$$i_{do} = \frac{E_{do} - \Psi_{do}}{x_b + x_d}$$

$$i_{qo} = -\frac{\Psi_{qo}}{x_b + x_q} \qquad (\mathbf{18})$$

After $t = 0$, the component of current in x_b due to closing the switch is

$$i_{d1} = -\frac{\Psi_{do}'}{x_{d23}(p)} = -\frac{i_{do} x_b + \Psi_{do}}{x_{d23}(p)}^{*}$$

$$i_{q1} = -\frac{\Psi_{qo}'}{x_{q23}(p)} = -\frac{i_{qo} x_b + \Psi_{qo}}{x_{q23}(p)} \qquad (\mathbf{19})$$

The component of current in x_b due to the change in δ is:

$$i_{d2} = -\frac{\Delta\Psi_d}{x_{d22}(p)}$$

$$i_{q2} = -\frac{\Delta\Psi_q}{x_{q22}(p)} \qquad (\mathbf{20})$$

The component of current in x_b due to a change in excitation voltage is:

$$i_{d3} = \frac{G(p)\Delta E_d}{x_{d12}(p)}$$

$$i_{q3} = 0 \qquad (\mathbf{21})$$

By superposition, the resultant current in x_b, after $t = 0$, is the algebraic sum of the components given by equations (**18**) to (**21**). Then

$$i_d = \frac{E_{do} - \Psi_{do}}{x_b + x_d} - \frac{i_{do} x_b + \Psi_{do}}{x_{d23}(p)} - \frac{\Delta\Psi_d}{x_{d22}(p)} + \frac{G(p)\Delta E_d}{x_{d12}(p)}$$

$$i_q = -\frac{\Psi_{qo}}{x_b + x_q} - \frac{i_{qo} x_b + \Psi_{qo}}{x_{q23}(p)} - \frac{\Delta\Psi_q}{x_{q22}(p)} \qquad (\mathbf{22})$$

Substituting equations (**22**) and (**4**) in (**2**) and simplifying

$$T = \frac{E_{do} e \sin \delta}{x_b + x_d} \left[\frac{x_b + x_d(p)}{x_{d12}(p)} \right]$$

---

[*] $x_{12}(p)$, $x_{13}(p)$, and $x_{23}(p)$ used hereafter are transfer impedances in operational form. $x_{22}(p)$ is a driving point impedance. See Appendix III of reference 6.

$$- \frac{e^2 \sin\delta \cos\delta_o}{x_b + x_d}\left[1 + \frac{x_d}{x_{d23}(p)}\right]$$

$$- \frac{e^2 \sin\delta}{x_{d22}(p)}(\cos\delta - \cos\delta_o)$$

$$+ \frac{e^2 \cos\delta \sin\delta_o}{x_b + x_q}\left[1 + \frac{x_q}{x_{q23}(p)}\right]$$

$$+ \frac{e^2 \cos\delta}{x_{q22}(p)}(\sin\delta - \sin\delta_o) + e \sin\delta \frac{G(p)}{x_{d12}(p)}\Delta E_d \qquad (23)$$

If the operators in the above expression are expanded by theorem (**11**), the equation for transient torque becomes

$$T = \frac{E_d e \sin\delta}{x_{d12}} + e^2 \frac{x_d - x_q}{2\, x_{d12} x_{q12}} \sin 2\,\delta$$

$$+ \frac{E_{do} e \sin\delta}{x_b + x_d} \frac{x_b\,(x_d - x_d'')}{x_{d12} x_{d12}''} \sum a_{dn} \epsilon^{-\alpha_{dn} t}$$

$$+ \frac{e^2 \sin\delta \cos\delta_o}{x_b + x_d} \frac{x_d\,(x_d - x_d'')}{x_{d12} x_{d12}''} \sum b_{dn} \epsilon^{-\alpha_{dn} t}$$

$$- e^2 \sin\delta \frac{x_d - x_d''}{x_{d12} x_{d12}''} \sum c_{dn} \epsilon^{-\alpha_{dn} t} (\cos\delta - \cos\delta_o)$$

$$- \frac{e^2 \cos\delta \sin\delta_o}{x_b + x_q} \frac{x_q\,(x_q - x_q'')}{x_{q12} x_{q12}''} \sum a_{qn} \epsilon^{-\alpha_{qn} t}$$

$$+ e^2 \cos\delta \frac{x_q - x_q''}{x_{q12} x_{q12}''} \sum b_{qn} \epsilon^{-\alpha_{qn} t} (\sin\delta - \sin\delta_o)$$

$$- \frac{e \sin\delta}{x_{d12}} \sum d_{dn} \epsilon^{-\alpha_{dn} t} \Delta E_d \qquad (24)$$

The above expression is the equation for the electrical torque developed by a synchronous machine subsequent to the occurrence of a balanced fault on the system accompanied by a change in angle from δ_o to δ and in excitation of ΔE. As in *Case 1* the electrical torque can be determined at any time of the rotor swing either by use of the step-by-step process or by the application of Duhamel's integral.

When x_f includes the equivalent reactance for unbalanced faults determined by the method of symmetrical components,[6,8] equation (**25**) will give the electrical torque if the additional assumption is made that the negative and zero phase sequence losses are negligible. If these losses are appreciable their effect may be included by the method given in Appendix B.

Case 2a. Constant Flux Linkages Maintained in Both Axes

As in *Case 1a* calculations may be greatly simplified, when justifiable, by making the assumption that the predominant rotor circuit of each axis has an infinite time constant and that all additional rotor circuits have zero time constants. If this assumption is made equation (**24**) may be simplified to the following expression:

$$T = \frac{E_{do} e}{x_{d12}'} \frac{x_b + x_d'}{x_b + x_d} \sin\delta + \frac{e^2}{2} \frac{x_d' - x_q'}{x_{d12}' x_{q12}'} \sin 2\,\delta$$

$$+ \frac{e^2}{x_{d12}'} \frac{x_d - x_d'}{x_b + x_d} \sin\delta \cos\delta_o$$

$$- \frac{e^2}{x_{q12}'} \frac{x_q - x_q'}{x_b + x_q} \cos\delta \sin\delta_o \qquad (25)$$

If $x_b = 0$ and $x_f = \infty$ equation (**25**) corresponds to equation (**46**) of reference 4 for sudden angular displacement.

II—Application of Mathematical Analysis

In the latter part of 1929, field tests* were made to determine the effect of amortisseur windings on the transient behavior of waterwheel generators following switching disturbances. Two machines were available for testing purposes; one had no additional rotor circuits other than a top field collar, and the other was provided with an incomplete copper amortisseur. The machines were otherwise identical. The results of these tests provide a means of checking the mathematical analysis given in Part I.

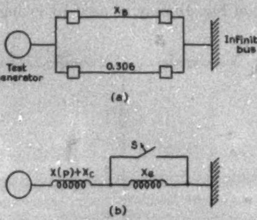

FIG. 3—TEST ARRANGEMENT AND EQUIVALENT CIRCUIT FOR SWITCHING OPERATION

The machine being tested was delivering power to a relatively large 110-kv. system through several circuits. A disturbance was created by opening all the circuits but one, which is a condition similar to that of *Case 1* in the first part of this paper.

In order to make use of equation (**13**) two assumptions as to the test set-up were necessary. These are:

a. The point of interconnection with the 110-kv. system can be considered as an infinite bus. Actually the infinite bus is farther back in the system. To

simplify calculations the finiteness of the bus was neglected with the knowledge that the value used for x_e would be too small.

b. The circuits opened during the test can be considered and treated as one equivalent circuit. These circuits actually consisted of a system network with other connected machines. The reactance of this equivalent circuit was then determined by the division of power. Before switching, the power factors of the two circuits were practically the same, so that this assumption is reasonable.

These assumptions made it possible to reduce the system to the one-line diagram in Fig. 3a which may be represented by the equivalent circuit in Fig. 3b. The rating of the test machines (9,000 kva.) was selected as the base per unit kva.

CHECK OF POWER OUTPUT OF MACHINE EQUIPPED WITH INCOMPLETE COPPER AMORTISSEUR

The following operational impedances of the machine equipped with an amortisseur were determined from the design data:

$$x_d(p) = 0.91 - \frac{1339p^5 + 778.2p^4 + 148.2p^3 + 10.98p^2 + 0.2545p}{1730p^5 + 1030p^4 + 202p^3 + 15.6p^2 + 0.396p + 0.000361}$$

$$x_q(p) = 0.524 - \frac{122.3p^3 + 32.4p^2 + 2.134p}{783.7p^3 + 263.2p^2 + 28.09p + 0.9202}$$

It was not necessary to determine $G(p)$ as the tests were made with constant field voltage ($\Delta E_d = 0$).

The inertia constant H was calculated from the design data and is equal to 1.79. Also $E_d = 1.19$, $e = 1.06$, $x_b = 0.058$, $x_c = 0.049$, $x_e = 0.257$ and initially $\delta_o = 19.62°$ and $T = 0.691$.

Substituting the machine and system impedances and the initial quantities in equation (13) the expression for torque output was obtained. The swing curve work sheet was set up (Table I) and the step-by-step calculations carried out according to Appendix A.

Fig. 4 presents a comparison between the calculated and test curves of electrical power output. The calculated initial drop in power was not quite as great as the test drop in power. The calculated oscillations are damped out somewhat faster than the test oscillations. Both of these errors can be largely accounted for by the fact that the assumed infinite bus is actually finite, and that the armature circuit resistance has been neglected.

Fig. 5 shows the calculated torque angle ellipse which describes the oscillation of the rotor for the first two swings. The marked points on the ellipse are points of equal time intervals.

CHECK OF POWER OUTPUT OF MACHINE WITH NO ADDITIONAL ROTOR CIRCUITS OTHER THAN A TOP FIELD COLLAR

From the design data of the second generator the following operational impedances were determined:

$$x_d(p) = 0.91 - \frac{0.7329p^2 + 0.1298p}{p^2 + 0.1994p + 0.0001940}$$

$$x_q(p) = 0.524$$

Also $H = 1.79$, $E_d = 1.19$, $e = 1.06$, $x_b = 0.046$, $x_e = 0.04$, $x_s = 0.266$ and initially $\delta_o = 19.36°$ and $T = 0.693$.

In a manner similar to that described in the preceding case, the swing of the rotor and the output of the machine were calculated. See Fig. 6 for a comparison between the test and calculated values of power output. Fig. 7 is the torque angle characteristic of this machine for the first two oscillations.

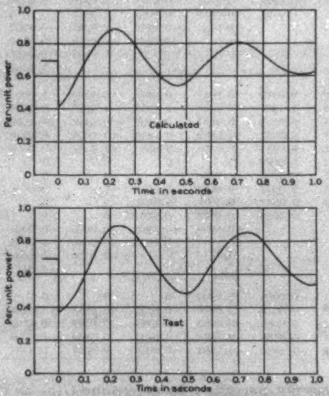

Fig. 4—Comparison of Calculated and Test Values of Transient Power (with Amortisseur)

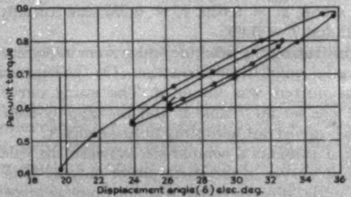

Fig. 5—Calculated Torque-Angle Characteristic (with Amortisseur)

Conclusion

Equations have been derived in this paper by which the transient behavior of a synchronous machine following the common types of system disturbances may be calculated. They are of sufficient generality that the effect of amortisseur windings or of excitation may be evaluated. Only such assumptions have been made in their derivation as are necessary to reduce them to a practical basis. If additional assumptions are made the equations may be reduced to the less general but more familiar equations of electrical torque derived by other authors. A comparison of the calculated and test results shows good agreement. The general equations may also be used as a basis for the derivation of more specific equations applying to particular conditions.

Appendix A

Step-by-Step Method

Step-by-step methods have been developed and explained in several other papers.[5,6,7] However a method well adapted for use with the general torque equations given in Part I is obtained from Duhamel's theorem* expressed as a summation rather than as an integral.

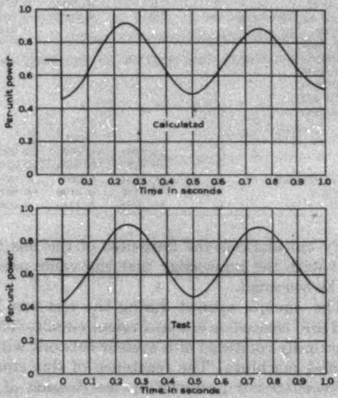

Fig. 6—Comparison of Calculated and Test Values of Transient Power (without Amortisseur)

In Fig. 8 the curve $F(t)$ represents any function of time which is to be operated on by an operator. In equation (**13**), for example, there are three such functions $(\cos \delta - \cos \delta_o)$, $(\sin \delta - \sin \delta_o)$ and ΔE. Let $T(t)$ represent the component of electrical torque produced by any one of these terms.

Then

$$T(t) = f(p)F(t) \qquad \textbf{(1a)}$$

where $f(p)$ = an operator

Let

$$F(\Delta t)_n = F(n\Delta t) - F[(n-1)\Delta t] \qquad \textbf{(2a)}$$

The curve $\delta(t)$ may be approached by assuming that at $t = 0$ a unit function $\delta(o)$ is suddenly impressed. After a time interval (Δt) a second unit function

---

*See Chapter XIV of "Heaviside's Operational Calculus," by E. J. Berg.

$\delta(\Delta t)_1$ is added. At the end of a second time interval a third unit function $\delta(\Delta t)_2$ is added, etc. The value of the function $T(t)$ at any time t is then equal to the sum of the torques due to $\delta(o)$ beginning at $t = 0$, $\delta(\Delta t)_1$ beginning at $t = \Delta t$, $\delta(\Delta t)_2$ beginning at $t = 2\Delta t$, etc. The torque due to $\delta(o)$ is $\delta(o) \cdot \phi(t)$ where $\phi(t)$ is the solution with unit function impressed at $t = 0$. The torque due to $\delta(\Delta t)_1$ is $\delta(\Delta t)_1 \cdot \phi(t - \Delta t)$. The torque due to $\delta(\Delta t)_2$ is $\delta(\Delta t)_2 \cdot \phi(t - 2\Delta t)$, etc.

$$\therefore T(t) = \delta(o) \cdot \phi(t) + \sum_{n=1}^{n=\infty} \delta(\Delta t)_n \cdot \phi(t - n\Delta t) \qquad \textbf{(3a)}$$

Equation (**3a**) provides a step-by-step method for obtaining the expansion of any terms containing operators operating on functions of the machine angle. All other terms containing operators operating on unit function alone may be expanded directly by equation (**11**). The procedure from this point on is similar to the ordinary swing curve calculation using the following equations given in Appendix IV of reference 6.

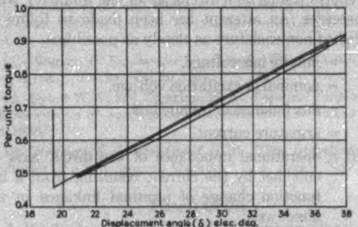

Fig. 7—Calculated Torque-Angle Characteristic (without Amortisseur)

$$T_a = T_m - T_E$$

$$\Delta\delta_1 = \frac{kT_a}{2}$$

$$\delta_1 = \delta_o + \Delta\delta_1$$
$$\Delta\delta_2 = \Delta\delta_1 + kT_1$$
$$\delta_2 = \delta_1 + \Delta\delta_2, \text{ etc.}$$

The details of the calculation may best be understood by reference to the sample swing curve calculation given in Part II.

Appendix B

Method for Determining the Torque Characteristics when Resistance is Included

It may be desirable to determine the influence of line and armature resistances upon the torque characteristic. Cases also arise in which the negative phase and zero phase sequence losses may be appreciable; as, for example, in the case of a machine having a high resistance amortisseur, or of a transformer having its neutral grounded through a resistor. The following method of analysis may be used to evaluate such factors.

If assumptions 4, 5, and 6 are made, equation (**5**) becomes

$$e_d = -ri_d - \Psi_q$$
$$e_q = -ri_q + \Psi_d \qquad \textbf{(1b)}$$

The effect of armature and line resistances may then be included in equivalent circuits for the direct and quadrature axes as shown in Fig. 9. Since an induced voltage and its corresponding flux linkages are in time quadrature with each other, current flowing through a resistance in one axis causes an equivalent flux linkage drop in the other axis. The directions in which these equivalent flux linkage drops are acting are indicated by arrows.

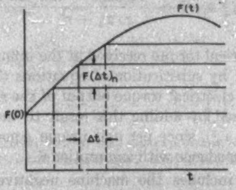

Fig. 8—Illustration of Step-by-Step Process

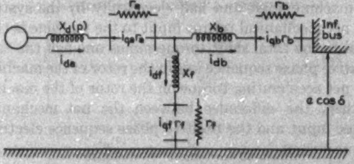
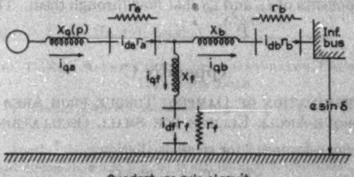


Direct axis circuit



Quadrature axis circuit

Fig. 9—Equivalent Flux Linkage Circuits Including Effect of Armature Circuit Resistance

As a simple example assume that $x_f = \infty$, $x_b = 0$, $r_b = 0$, constant flux linkages are maintained in the main field winding and there are no additional rotor circuits. Then

$$x_d(p) = x_d'$$
$$x_q(p) = x_q' = x_q$$

From Fig. 9 the following relations can be written

$$\Psi_d' - e\cos\delta = i_q r + i_d x_d'$$
$$e\sin\delta = i_q x_q - i_d r \qquad \textbf{(2b)}$$

where

Ψ_d' = constant value of flux linkages in the main field.

Solving equations (**2b**) simultaneously

$$i_d = \frac{\Psi_d' x_q - e x_q \cos\delta - er\sin\delta}{x_d' x_q + r^2}$$

$$i_q = \frac{\Psi_d' r - er\cos\delta + e x_d' \sin\delta}{x_d' x_q + r^2} \qquad \textbf{(3b)}$$

The electrical torque received at the infinite bus may be obtained by substitution of equations (**3b**) and (**4**) in (**2**). The electrical torque output of the machine can be determined by adding this result to the resistance loss $r\,(i_d^2 + i_q^2)$, since per unit torque equals per unit power in accordance with assumption 6.

When r_f includes the machine negative phase sequence resistance (r_2), half of the negative phase resistance loss in the rotor is supplied mechanically by the machine shaft and half electrically by the system. The net mechanical torque input to the machine is then equal to the total shaft torque minus one-half the total negative phase sequence loss in the rotor of the machine. The net accelerating torque on the rotor of the machine is, then, the difference between the net mechanical torque input and the positive phase sequence electrical torque output.

The zero phase sequence loss can be determined by including in r_f the proper components of zero phase sequence resistance and by evaluating the zero phase components of i_{df} and i_{qf} that flow through them. Then

$$P_o = r_o\,(i_{dfo}^2 + i_{qfo}^2) \qquad \textbf{(4b)}$$

Appendix C

DETERMINATION OF DAMPING TORQUE FROM AREA OF TORQUE-ANGLE ELLIPSE FOR SMALL OSCILLATIONS

From reference 2 for small oscillations:

$$\Delta T = T_s\Delta\delta + T_d p\Delta\delta \qquad \textbf{(1c)}$$

Since the oscillation of one machine with respect to a system is nearly harmonic, the angle of oscillation about the mean may be approximately expressed by

$$\Delta\delta = -\,[\Delta\delta]\cos st \qquad \textbf{(2c)}$$

where $[\Delta\delta]$ is the maximum deviation and $s/2\pi$ is the frequency of oscillation.

Substituting equation (**2c**) in (**1c**)

$$\Delta T = -\,T_s\,[\Delta\delta]\cos st + sT_d\,[\Delta\delta]\sin st \qquad \textbf{(3c)}$$

The area of the ellipse is:

$$A = \int_{\theta=0}^{\theta=2\pi} \Delta T d(\Delta\delta) \qquad \textbf{(4c)}$$

where $\theta = st.$

Substituting (**3c**) in (**4c**):

$$A = \int_0^{2\pi} \{-\,T_s\,[\Delta\delta]\cos\theta + sT_d\,[\Delta\delta]\sin\theta\}\,[\Delta\delta]\sin\theta\, d\,\theta \qquad \textbf{(5c)}$$

which reduces to $A = \pi s T_d\,[\Delta\delta]^2$

giving

$$T_d = \frac{A}{\pi s\,[\Delta\delta]^2} \qquad \textbf{(6c)}^*$$

NOMENCLATURE

All quantities are expressed as a fraction of their normal values which are per unit values as defined in reference 3. The subscripts d and q refer to the direct and quadrature axes respectively. The subscript o specifies initial steady state conditions. The coefficient Δ denotes the increment change of the quantity which it precedes. An attempt has been made to follow established nomenclature as closely as possible.

e = infinite bus voltage.

E = nominal or excitation voltage.

Ψ = flux linkages of infinite bus.

i = armature current.

$x_d(p)$ = operational impedance of the direct axis circuit met by the current resulting from a unit function change of terminal linkages in the direct axis.

$x_q(p)$ = operational impedance of quadrature axis circuit.

$G(p)$ = an operator which relates field voltage with current and linkages in the direct axis.

p = an operator d/dt.

δ = displacement angle of the nominal voltage from the infinite bus voltage expressed in electrical radians. It is the actual space phase lag or lead of the rotor.

s = per unit frequency of rotor oscillations.

θ = angle in electrical degrees between the axis of the rotor and a stationary axis in space.

t = time expressed as a fraction of the time to pass one electrical radian at fundamental frequency. Unit time is thus $1/2\pi f$.

n = a subscript denoting any field circuit, also denoting any time interval.

r = armature circuit resistance.

T_o' = open circuit time constant in radians.

x† = synchronous reactance.

x'† = transient reactance.

x''† = sub-transient reactance.

---

*This expression was derived by I. H. Summers.

†NOTE: These values of reactance include certain reactances external to the machine terminals which differ depending upon the conditions of the case considered.

Discussion

J. W. Butler: Messrs. Crary and Waring have done a creditable piece of work in making available equations for determining the transient characteristics of synchronous machines, giving in particular, due consideration to every rotor circuit. The power oscillations were checked accurately by a step-by-step solution using the general torque equation (13) of the text. The solution was perfectly general within the assumptions, without dividing the torque into its components, generally spoken of as synchronizing and damping torques.

However, if it is desired to calculate the damping torque for comparatively large sustained oscillations, it can be obtained from the general equation (13) as follows:

Let the change in the angle δ, be of the form

$$\Delta\delta = [\Delta\delta] \sin st$$

Then, by use of the superposition theorem, the response of the system can be found to this variation in angle. In order to integrate the resultant expression, represent the sine and cosine terms, by the first two terms of the series, such as

$$\cos [(\Delta\delta) \sin st] = 1 - \frac{[(\Delta\delta) \sin st]^2}{2\,!}$$

$$\sin [(\Delta\delta) \sin st] = (\Delta\delta) \sin st - \frac{[(\Delta\delta) \sin st]^3}{3\,!}$$

Using these forms in the transient terms of equation (13), due to the unit function change in δ, and applying the superposition theorem there is obtained an expression for torque, for a sinusoidal change in angle. Due to the fact that a sustained oscillatory condition is being considered only the sustained terms are to be retained in this expression. Integrating the sustained terms, with respect to st, from o to 2π, the area of the torque angle ellipse is obtained. Dividing the resultant expression for area by $\pi s\,(\Delta\delta)^2$ as shown in Appendix C, the expression for the damping torque coefficient is obtained. The above procedure was carried out and is too bulky to include here but the final result is

$$T_d = e^2 \frac{x_d - x_d''}{x_d x_d''} \sum b_{dn}\alpha_{dn} \left\{ \frac{\sin^2\delta_o'}{\alpha_{dn}^2 + s^2} \left[1 - \frac{(\Delta\delta)^2}{8} \right] \right.$$

$$\left[1 - \frac{(\Delta\delta)^2}{6\,(\alpha_{dn}^2 + 9s^2)} \left(\frac{3\alpha_{dn}^2 + 3s^2}{4} + 6s^2 \right) \right]$$

$$\left. + \frac{(\Delta\delta)^2}{4} \frac{\cos^2\delta_o'}{\alpha_{dn}^2 + 4s^2} \left[1 - \frac{(\Delta\delta)^2}{12} \right] \right\}$$

$$+ e^2 \frac{(x_q - x_q'')}{x_q x_q''} \sum b_{qn}\alpha_{qn} \left\{ \frac{\cos^2\delta_o'}{\alpha_{qn}^2 + s^2} \left[1 - \frac{(\Delta\delta)^2}{8} \right] \right.$$

$$\left[1 - \frac{(\Delta\delta)^2}{6(\alpha_{qn}^2 + 9s^2)} \left(\frac{3\alpha_{qn}^2 + 3s^2}{4} + 6s^2 \right) \right]$$

$$\left. + \frac{(\Delta\delta)^2}{4} \frac{\sin^2\delta_o'}{\alpha_{qn}^2 + s^2} \left[1 - \frac{(\Delta\delta)^2}{12} \right] \right\}$$

It is of interest to note that this expression, letting $[\Delta\delta] = o$, checks Park's results in reference 2, derived in a different manner.

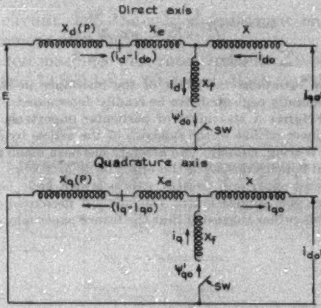

FIG. 1—EQUIVALENT CIRCUIT OF A GENERATOR FEEDING AN IMPEDANCE LOAD

Closing switch *SW* simulates a three-phase fault on feeder

Another thing which I feel should be emphasized is the equivalent circuit shown in Fig. 9. It can be used to calculate any sort of a transient in a machine, including resistance, within the assumptions made. One particular use I have made of the circuit is in calculating decrement curves, for a fault on a generator feeding an impedance load, considering the effect of the load resistance in the time constants and magnitudes of the current. For this application the circuit reduces to that shown in Fig. 1.

Relative to Fig. 1, the following linkage equations may be written.

$$\Psi_{do}' + i_{qo}r = xi_{do} + i_d x_f$$
$$\Psi_{do}' = (i_d - i_{do})\,[x_e + x_d\,(p)] + i_d x_f$$
$$\Psi_{qo}' - i_{do}r = i_q x_f + i_{qo}x$$
$$\Psi_{qo}' = i_q x_f + (i_q - i_{qo})\,[x_e + x_q\,(p)]$$

where

i_d = fault current direct axis
i_{do} = load current direct axis
i_q = fault current quadrature axis
i_{qo} = load current quadrature axis

x = load reactance
r = load resistance
x_f = fault reactance
x_e = external reactance
$x(p)$ = operational impedance of generator
Ψ' = linkage at point of fault, before fault occurred.

Solving these, there is obtained for the fault currents

$$i_d = \frac{\Psi_{do}' \left[x\,(x + a)\,x_{q31}\,(p) + r^2\,(x_f + b)\right] + \Psi_{qo}' rab}{D(p)}$$

$$i_q = \frac{\Psi_{qo}' \left[x\,(x + b)\,x_{d31}\,(p) + r^2\,(x_f + a)\right] - \Psi_{do}' rab}{D(p)}$$

where

$$a = x_e + x_d\,(p)$$
$$b = x_e + x_q\,(p)$$
$$D(p) = x^2 x_{d31}\,(p)\,x_{q31}\,(p) + r^2\,(x_f + a)\,(x_f + b)$$

Solving these operational equations by the expansion theorem there is obtained

$$i_d = I_d + (I_d'' - I_d) \sum b_{dn}\,\epsilon^{-\alpha_n t}$$
$$i_q = I_q + (I_q'' - I_q) \sum b_{qn}\,\epsilon^{-\alpha_n t}$$
$$\alpha_n = \text{roots of } D(p) = o$$
$$b_n = \frac{1}{(I'' - I)}\;\frac{Y\,(\alpha_n)}{\alpha_n\,Z'\,(\alpha_n)}$$
$$\sum b_n = 1.0$$

From these equations the effect of the resistance in the load, which is generally neglected, can be readily determined.

S. H. Wright: A statement of particular importance to the utility engineer is that in the synopsis of the article by Messrs. Crary and Waring, namely, "No attempt has been made to draw any general conclusions as to the effect of amortisseurs . . . . A subsequent paper will present results which have been obtained from the application of the method presented in this paper." This rather suggested that the future paper may discuss the more general problem of determining the most suitable type of damper winding for specific applications. In this regard, the following discussion is thought to be pertinent.

Certain of the prime advantages of low and high resistance dampers are as follows:

1. Low-resistance dampers tend rapidly to damp out swings which occur during symmetrical circuit conditions (that is where current magnitudes are equal in the three phases).

2. For two-machine stability problems (or multi-machine problems, where there are no serious compound oscillations) high-resistance dampers give higher transient stability limits, especially for the longer clearing times, such as greater than 16 cycles where f = 60 cycles per sec. This was brought out by C. F. Wagner, (see item 11 of bibliography of Crary and Waring paper, particularly Fig. 3 of this reference). However, this gain is apparently negligible for fault durations of the order of 8 cycles or less, and 8 cycles clearing time is being successfully obtained with modern high-speed circuit breakers and relays. The higher the speed of clearing any type of line fault, the more the entire occurrence approaches merely the condition of switching out a circuit.

In years to come it is likely that the average high-voltage system will reduce its clearing time to 8 cycles or less and it is possible that at the same time, interconnections and other factors will make compound system oscillations more important; in such a case the greater damping ability, under symmetrical circuit conditions, of low-resistance dampers would become of paramount importance.

S. B. Crary: Mr. Butler has made an interesting application of the general torque equations. His solution is limited to a forced oscillation such as is obtained in a compressor drive and is interesting in that it can be applied to large angular deviations.

Mr. Wright's conclusions concerning the influence of decreased switching times on the gains to be realized from high and low resistance amortisseur windings correspond with our opinions. When the switching times are very short, a high resistance amortisseur is of slight benefit in improving stability limits. On the other hand, the low resistance amortisseur is of aid in damping out all angular oscillations and is generally beneficial.

Field Tests to Determine the Damping
Characteristics of Synchronous Generators

BY F. A. HAMILTON, Jr.*

Associate, A.I.E.E.

***Synopsis.**—Practical system tests of the damping action of generators with and without low resistance damper windings, but otherwise identical, have been made. The effects of normal variations of generator field circuit resistance, field current, and loading, were investigated. Data for checking calculated machine constants also were obtained. The tests results are valuable from a quantitative, as well as from a qualitative standpoint.*

* * * * *

INTRODUCTION

IN the School Street Station of the New York Power and Light Corporation there are two waterwheel-driven generators which, originally, were identical 40-cycle units. Early in 1927 one of these machines was rebuilt for 60-cycle operation. Later in the same year the rebuilding of the companion unit was undertaken.

Meanwhile arguments for and against the use of damper windings were advanced; it was becoming apparent that comparative tests on an actual system might help to determine their effect upon transient power limits.

FIG. 1—ARRANGEMENT OF CIRCUITS AND EQUIPMENT

The idea of adding damper windings to the second machine to be rebuilt for 60-cycle operation, and of comparative tests on this and on the machine already rebuilt without them, was broached to the New York Power and Light Corporation. As a result, low-resistance damper windings were installed in the second machine to be rebuilt, and plans for testing were developed.

Force of circumstances ultimately prevented extensive tests to establish relative power limits for various types of short circuits of different durations. But less severe tests to check the validity of existing methods of analysis, and to further the development of damping theory, were finally completed late in 1929.

This paper describes these tests, and includes a resumé of the data obtained. Evidence of the accuracy of available methods of calculating machine constants is presented. The effectiveness of damper windings in rapidly smoothing out balanced disturbances is shown. In a companion paper, a method of predicting generator behavior during disturbances is developed, and calculations based on this method verified by comparison with the test data.[1]

DESCRIPTION OF TESTS

The circuits, and the major equipment employed, were arranged as in Fig. 1.

Both test machines were rated 7,200 kw., 9,000 kva., 180 r.p.m., 13,800 volts, 60-cycles. Both machines had top field collars. One had no damper windings. The other was equipped with low-resistance damper windings of the type shown in Fig. 2.

		No	0+	200		0.92	1.12

*Field current required to produce rated open-circuit voltage is approximately 180 amperes.

constants. For these tests the procedure was to (1) connect the test generator to the system, (2) operate it at no-load in an under-excited condition and, 3) suddenly disconnect it from the system. Fig. 3 comprises oscillographic records of the ensuing phenomena, the field current curves being of particular interest.

The remaining items in Table I refer to tests which were made to determine the relative damping characteristics of the two machines. For these tests the procedure was to connect the test generator to the test bus, load it and the test circuits in predetermined fashion, and trip the bus tie breaker thus initiating a balanced disturbance with the test machine remaining connected to the main system by means of a single circuit. Figs. 4 and 5 comprise typical oscillographic records of such tests, the oscillatory power curves being of particular interest.

The same exciter and excitation circuits were used for all tests. Voltage regulators were not used. Prior to each test the generator field rheostat was adjusted to give the desired value of generator field circuit resistance. The desired value of generator field current was then obtained by manual manipulation of the exciter field rheostat.

The voltage of the main system bus varied but little during the testing period, and during each individual test remained practically unchanged.

MACHINE CONSTANTS

The constants of each test machine were calculated from design data in the manner described by Linville.[2] Using these values and an operational method outlined by Park,[3] the action of each machine's field current was calculated for the conditions existing while the records of Fig. 3 were being obtained. In Fig. 6 the calculated curves are compared with those taken from the oscillographic records of Fig. 3.

In developing the calculated field current curves, direct axis constants were used; quadrature axis constants were not used because the tests to be checked were made at no-load. The excellent agreement between the calculated and test curves indicates the accuracy of the method used to derive the direct axis constants. The same method was used to calculate the quadrature axis constants. Thus, the reasonable-

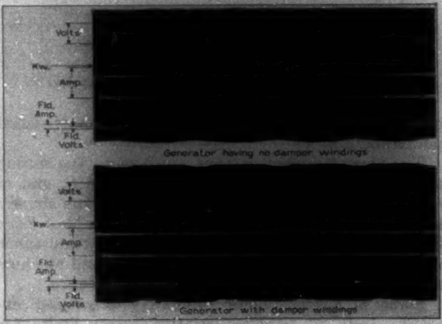

FIG. 3—OSCILLOGRAPHIC RECORDS OF MACHINE CONSTANT TESTS

ness of the calculated machine constants, used by the authors of the companion paper[1] in theoretically checking the power swing records of Fig. 4, is indicated.

The more important constants of the two test machines are given in Table II.

DAMPING TORQUE COEFFICIENTS

The time required for the damping of a balanced disturbance to $\frac{1}{\epsilon}$ of its initial value is inversely proportional to the damping torque coefficient, T_d, which can be determined from test records by the method given in the Appendix. In this way the damping torque coefficient was determined for each of the tests referred to in items 2 to 10 of Table I.

These results are plotted in Figs. 7 and 8, both of which show the relative damping action of machines with and without low resistance damper windings of the type shown in Fig. 2. The damping torque coefficients for the damping winding machine are, approximately, three times those of the other machine. The major portions of power oscillations involving the damper winding machine were damped out in about one-third of the time required for the damping out of like oscillations involving the machine not equipped with these windings.

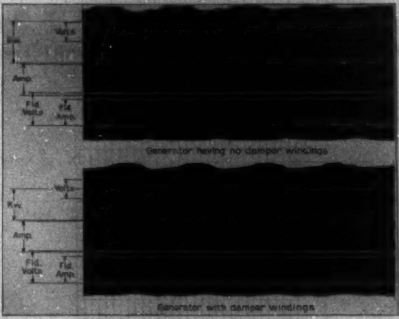

FIG. 4—OSCILLOGRAPHIC RECORDS OF DAMPING TESTS—LOADED CONDITIONS

TABLE II—CALCULATED MACHINE CONSTANTS

Constant	With damper windings	No damper windings
x_d	0.91	0.91
x_d'	0.26	0.26
x_d''	0.14	0.177
x_q	0.524	0.524
x_q'	0.524	0.524
x_q''	0.368	0.524
T_{do}'	2.86 (sec.)	2.86 (sec.)
T_{do}''	0.055 (sec.)	0.0136 (sec.)
T_{qo}''	0.044 (sec.)	
H	1.78 (sec.)	1.78 (sec.)

A comparison of the power swings shown in Fig. 4, and a comparison of those shown in Fig. 5, provide a more graphic illustration of the increased rapidity with which balanced disturbances are damped out when machines are equipped with low-resistance damper windings.

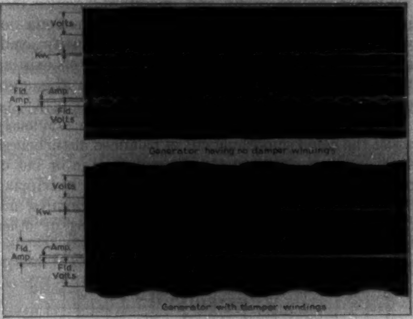

FIG. 5—OSCILLOGRAPHIC RECORDS OF DAMPING TESTS—LIGHTLY LOADED CONDITIONS

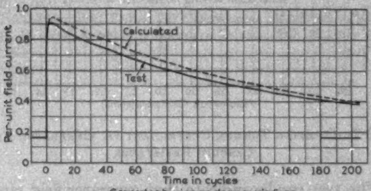
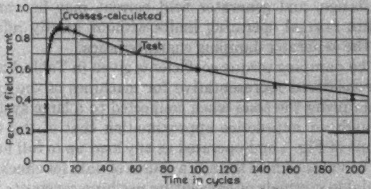


Generator having no damper windings



Generator with damper windings

FIG. 6—MACHINE CONSTANT TESTS—COMPARISON OF CALCULATED AND TEST RESULTS

Fig. 7 also shows that damping varies but little with normal values of generator field circuit resistance. Fig. 8 also shows that damping varies inappreciably with values of generator field current within normal operating limits.

The effect of generator loading can be judged by comparing the values of T_d given in item 10 of Table I with values of T_d tabulated for other tests. For the machine with damper windings T_d was approximately the same, regardless of the average load. For the machine having no damper windings, T_d during no-load operation was only about one-half as great as with the machine loaded.

CONCLUSIONS

Field tests are useful and important because they provide graphic evidence concerning phenomena not well understood, and data with which to verify available methods of analysis, or extensions of existing theory. Both purposes were fulfilled by the tests described.

Low-resistance damper windings quite obviously assist the rapid smoothing out of balanced disturbances such as occur owing to (1) the switching in or out of lines, (2) synchronizing, (3) load changes or the tripping of loaded generators, (4) three-phase short circuits, and (5) the occurrence and subsequent clearing of other types of faults.

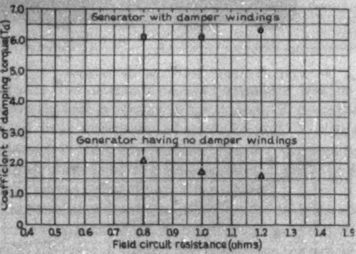


FIG. 7—DAMPING TORQUE COEFFICIENT VS. GENERATOR FIELD CIRCUIT RESISTANCE

The test results indicate that generator field circuit resistance, and generator field current may be varied within normal operating limits without greatly affecting the generator damping characteristics.

The damping torque coefficients given in Table I may be considered representative for machines of the type used during the tests when connected to a large system through an impedance approximating that of the test circuit of Fig. 1 and operated at any load up to full load.

The value of field tests as a source of data for checking available methods of calculating machine constants has been shown. The importance of field tests as a source of data for verifying the theory employed to predetermine the action of machines during system disturbances is shown by the companion paper.[1]

The New York Power and Light Corporation is deserving of much credit for the results of these tests, for which it made available a portion of its system, and in the carrying out of which Mr. Powell, Mr. Bromeson, and other members of its staff provided material assistance.

Appendix

DETERMINATION FROM TEST RECORDS OF DAMPING TORQUE COEFFICIENTS

The electrical torque of a synchronous machine during an oscillation may, in an approximate manner, be separated into two components. These are the damping and the synchronizing torques. If the oscillations are small the synchronizing torque at any instant is very nearly proportional to the angular displacement of the generator rotor. Under such conditions this, torque may be represented by a constant, T_s, times the angular displacement. The damping torque depends upon the rate of change of angle and may be represented by a constant, T_d, times the rate of change of angular displacement.

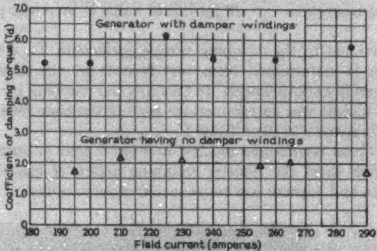

FIG. 8—DAMPING TORQUE COEFFICIENT VS. GENERATOR FIELD CURRENT

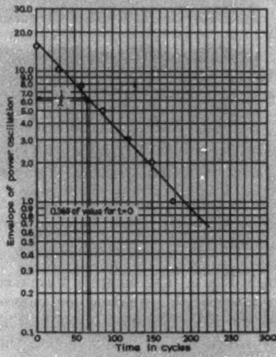

FIG. 9—DETERMINATION OF TIME CONSTANT OF POWER OSCILLATION DECREMENT

Multiply cycles by 2π to obtain $\frac{1}{l}$ in radians before substituting in equation (3)

The differential equation for the motion of a generator rotor with constant mechanical torque input, and small angular displacement, is approximately

$$4\pi f H \frac{d^2\delta'}{dt^2} = -T_s\delta' - T_d\frac{d\delta'}{dt} \tag{1}$$

where

f = system frequency in cycles per second.

H = inertia constant of the machine, or

$$\frac{0.231\ WR^2\left[\frac{\text{r.p.m.}}{1{,}000}\right]^2}{\text{Base kw.}}\ (\text{Sec.}).$$

δ' = angle in electrical radians of the rotor from the final angle of equilibrium.

T_s = coefficient of synchronizing torque, *i. e.*, per unit torque per radian of angular displacement.

T_d = coefficient of damping torque, *i. e.*, per unit torque per radian of angular displacement per radian time.

t = time measured in radians, *i. e.*, unit time is the time required for the rotor to pass one electrical radian at fundamental frequency (f).

The solution of equation (**1**), when $\frac{d\delta'}{dt} = 0$, and $\delta' = -\delta_0'$, at $t = 0$, is

$$\delta' = -\delta_0'\,\epsilon^{-lt}\cos st \tag{2*}$$

where

δ_0' = the initial angular displacement of the rotor from the final angle of equilibrium,

$$l = \frac{T_d}{8\pi f H} \tag{3}$$

$$s = \sqrt{\frac{T_s}{4\pi f H} - \left[\frac{T_d}{8\pi f H}\right]^2} \tag{4}$$

Since the maximum and minimum values of displacement angle will occur approximately simultaneously with the maximum and minimum values of electrical power, the time constant of the decrement of the power envelope equals $\frac{1}{l}$ which is determined from a plot on semi-log paper of the power oscillation as shown by Fig. 9. Therefore, T_d can be obtained directly from equation (**3**) and the test oscillographic record of electrical power.

Design of Capacitor Motors for Balanced Operation

BY P. H. TRICKEY*

Associate, A.I.E.E.

INTRODUCTION

THE present methods of calculating the full load performance of capacitor motors are quite long and tedious. This paper presents a simple, convenient method of calculating full-load conditions.

It is generally agreed that a capacitor motor should be designed to operate under nearly balanced conditions at full load, meaning by this that there shall be no transfer of power from one phase to the other and balanced currents in the rotor. With such a design, each phase produces equal flux and the rotor operates as if in a two-phase stator.

METHOD OF OBTAINING BALANCED CONDITIONS

An attempt is sometimes made to approximate balanced conditions by making the voltages applied to each phase 90 electrical degrees apart and proportional to the turns in the windings. However, it is obvious that in order to obtain true balanced conditions, the field produced by each phase must be of the same magnitude and 90 degrees apart. If this is true, the rotor currents will also be of the same value and displaced 90 degrees. Under such conditions, the induced voltage, and not the applied voltage must be balanced. The magnetizing current being proportional to the induced voltage, it will, therefore, also be balanced and the primary currents as well as the secondary currents will be 90 degrees displaced and inversely proportional to the effective turns. Fig. 1 shows the vector diagram for a capacitor motor.

As a general rule the main winding has been determined by the necessary maximum torque of the motor. This in turn determines the primary resistance, and the current in the main phase. It remains, therefore, to determine the number of turns in the capacitor phase, the size of wire and the impedance of the capacitor itself. Since the resistance of the capacitor is controlled by the available space for it, and the allowable loss, the designer can usually estimate fairly closely as to its value. It will be treated hereafter as a known constant and if necessary the motor may be redesigned when the resistance of the capacitor differs from the assumed value. Thus, there are three variables to be determined, number of turns, size of wire, and capacitive reactance.

SOLUTION OF THE VECTOR DIAGRAM

Under the first necessary condition, the two fluxes must be alike. If this is the case the induced voltages in each phase must be 90 deg. apart, and their magnitudes must be in the ratio of the effective conductors in each phase.

$$e_{2S} = jKe_{2m} \tag{1}$$

where

e_{2S} = induced voltage in the capacitor phase

e_{2m} = induced voltage in the main phase

$K = \dfrac{\text{effective conductors in capacitor phase}}{\text{effective conductors in main phase}}$

j = operator to revolve vector 90 deg.

Under the second necessary condition, the two primary currents must be 90 deg. apart and their magnitudes must be in the inverse ratio of the effective conductors.

$$I_{1S} = \frac{j}{K}\, i_{1m} \tag{2}$$

Where

i_{1S} = primary current in capacitor phase

i_{1m} = primary current in main phase

$$E_S = e_{2S} + i_{1S}Z_{1S} \tag{3}$$

Where

E_S = capacitor phase voltage

Z_{1S} = primary impedance of capacitor phase

But

$$E_S = E_M - i_{1S}Z_c \tag{4}$$

Where

E_m = main phase and line voltage

Z_c = impedance of capacitor

(*a*) *Solution of equation* (**3**)

$$E_S = jKe_{2m} + \left(\frac{j}{K}\, i_{1m}\right)(Z_{1S})$$

But

$Z_{1S} = r_{1S} + jX_{1S}$

Where

r_{1S} = primary resistance of capacitor phase

X_{1S} = primary reactance of capacitor phase

If the winding distribution is the same in each phase

$$X_{1s} = K^2X_{1m}$$
$$r_{1s} = KK_a r_{1m}$$

Where

$K_a = \dfrac{\text{area of conductor in main phase}}{\text{area of conductor in capacitor phase}}$

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

32-106

r_{1m} = primary resistance of main phase
X_{1m} = primary reactance of main phase

$$E_s = jKe_{2m} + \left(\frac{j}{K}\, i_{1m}\right)(KK_a r_{1m} + jK^2 X_{1m})$$

$$= jKe_{2m} - KX_{1m} i_{1m} + jK_a r_{1m} i_{1m}$$

But

$$e_{2m} = E_m - i_{1m} Z_{1m}$$

$$E_s = jKE_m - jKi_{1m}(r_{1m} + jX_{1m}) - KX_{1m} i_{1m} + jK_a r_{1m} i_{1m}$$

$$= jKE_m - jKi_{1m} r_{1m} + jK_a r_{1m} i_{1m}$$

It will be noted that X_{1m} drops out at this point eliminating the question of dividing the leakage reactance into primary and secondary components.

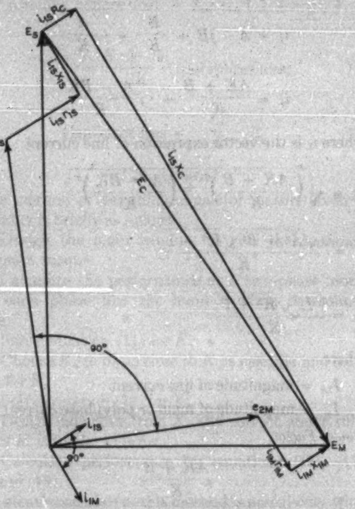

Fig. 1—Vector Diagram of Capacitor Motor Under Balanced Operating Conditions

For simplification, let

$$i_{1m} = A - jB$$

Where
A = power component of main phase primary current
= I_m times power factor
B = reactive component of main phase primary current
= $\sqrt{I_m^2 - A^2}$

I_m is the phase current as determined by calculating the motor as a two-phase motor with each phase identical to the main winding of the capacitor.

$$E_s = K_a B r_{1m} - KBr_{1m} + j(KE_m + K_a A r_{1m} - KAr_{1m}) \qquad (5)$$

(*b*) *Solution of equation* (**4**)

$$E_s = E_m - i_{1s} Z_c$$

$$Z_c = R_c - jX_c$$

Where
R_c = effective resistance of capacitor
X_c = effective capacitive reactance of capacitor (positive)

$$E_s = E_m - \frac{j}{K}(A - jB)(R_c - jX_c)$$

$$= E_m - BR_c/K - AX_c/K + j(BX_c/K - AR_c/K) \qquad (6)$$

Since these two equations for E_s must be identical, the components must be equal.

Horizontal Components

$$E_m - BR_c/K - AX_c/K = K_a B r_{1m} - KBr_{1m}$$

$$KE_m - BR_c - AX_c = KK_a B r_{1m} - K^2 B r_{1m} \qquad (7)$$

Vertical Components

$$BX_c/K - AR_c/K = KE_m + K_a A r_{1m} - KAr_{1m}$$

$$BX_c - AR_c = K^2 E_m + KK_a A r_{1m} - K^2 A r_{1m} \qquad (8)$$

Multiplying by B and A respectively in equations (**7**) and (**8**) and eliminating X_c.

$$K^2[AE_m - r_{1m}(A^2 + B^2)] - K[BE_m - K_a r_{1m}(A^2 + B^2)] + (A^2 + B^2) R_c = 0 \qquad (9)$$

Since this quadratic equation gives a difficult solution to use, a cut and try method is followed.

$$K[AE_m - r_{1m}(A^2 + B^2)] = [BE_m - K_a r_{1m}(A^2 + B^2)] - (A^2 + B^2) R_c/K$$

$$K = \frac{BE_m - K_a r_{1m}(A^2 + B^2) - (A^2 + B^2) R_c/K}{AE_m - r_{1m}(A^2 + B^2)} \qquad (10)$$

But $A^2 + B^2 = I_m^2$ where I_m is the magnitude of i_{1m}

$$K = \frac{BE_m - K_a r_{1m} I_m^2 - (R_c/K) I_m^2}{AE_m - r_{1m} I_m^2} \qquad (11)$$

In the above equation everything has been determined by the design of the main winding except K and K_a. The method of using this equation is as follows: K_a must, of course, be a function of $\sqrt[3]{2}$ since wire sizes vary in this definite ratio. The usual motor will have one, two, or three wire sizes smaller than the main winding, and thus K_a will be 1.26, 1.59, or 2.00. One of these is assumed, and since, as will be shown later, K should be somewhere near equal to K_a, the value of K on the right-hand side of equation (**11**) is taken equal to the assumed value of K_a. The equation is then solved for K. The value of K obtained is substituted for the assumed value and a second solution is made. Since the third term is usually small, it is seldom necessary to make more than two solutions. For every value of K_a, there will be a definite value of K, or in other words, there are as many balanced motors as there are wire sizes. However, the change in K for different values of K_a is very small. Fig. 2 shows the effect of changing K_a upon the constants and performance of a typical motor. It will be noted that the only values which change in any great degree are the weight of wire and the current density, and that whatever gain is made in reducing capacitor phase copper is made at the expense of a higher current density in the capacitor winding. It would seem desirable, therefore, to choose K as nearly equal to K_a as wire sizes will permit.

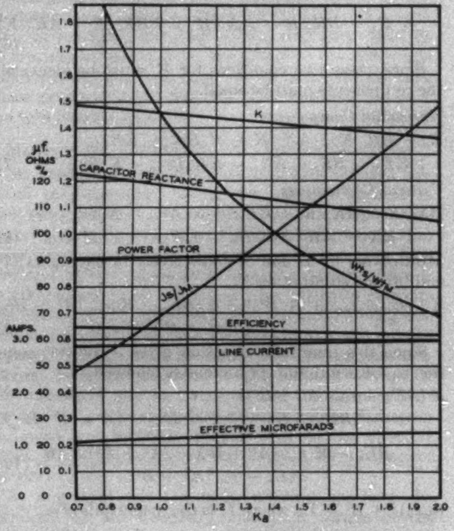

Fig. 2—Effect of K_a on Capacitor Motor Performance

$Ka = \frac{\text{area of conductor in main phase}}{\text{area of conductor in capacitor phase}}$

$K = \frac{\text{effective conductors in capacitor phase}}{\text{effective conductors in main phase}}$

$\frac{J_s}{Jm} = \frac{\text{current density in capacitor phase}}{\text{current density in main phase}}$

$\frac{Wt_s}{Wtm} = \frac{\text{total weight of wire in capacitor phase}}{\text{total weight of wire in main phase}}$

Having determined K from equation (**11**), equation (**7**) gives,

$$X_c = \frac{KE_m - BR_c - KK_a Br_{1m} + K^2 Br_{1m}}{A} \qquad (12)$$

$$C = \frac{10^6}{2\pi f X_c} \text{ or } \frac{2650}{X_c} \text{ for 60 cycles} \qquad (13)$$

where C = effective microfarads

$$E_c = \frac{I_m Z_c}{K} = \text{voltage across capacitor} \qquad (14)$$

Performance Calculation of Balanced Motor

Since the motor has been designed to have rotor conditions identical to a two-phase motor with each phase like the main phase of the capacitor motor, the motor may be calculated like a polyphase motor. There will be, however, differences in some of the performance values.

Line Current

$$i_L = i_{1m} + i_{1c} = i_{1m} + \frac{j}{K} i_{1m}$$

$$i_L = A - jB + \frac{B}{K} + j\frac{A}{K}$$

$$i_L = \frac{AK + B}{K} + j\frac{A - BK}{K}$$

where i_L is the vector expression of line current

$$I_L = \sqrt{\left(\frac{AK + B}{K}\right)^2 + \left(\frac{A - BK}{K}\right)^2}$$

$$= \frac{\sqrt{A^2 + B^2}\sqrt{K^2 + 1}}{K}$$

$$I_L = \frac{I_m\sqrt{K^2 + 1}}{K} \qquad (15)$$

where

I_L = magnitude of line current

I_m = magnitude of main or polyphase current

Power Factor

$$\text{P. F.} = \frac{\frac{AK + B}{K}}{\sqrt{\left(\frac{AK+B}{K}\right)^2 + \left(\frac{A-BK}{K}\right)^2}}$$

$$= \frac{AK + B}{\sqrt{A^2 + B^2}\sqrt{K^2 + 1}}$$

$$\text{P. F.} = \frac{AK + B}{I_m\sqrt{K^2 + 1}} \qquad (16)$$

or

$$\frac{A + \frac{B}{K}}{I_L} \qquad (17)$$

The losses of the capacitor motor will differ from the losses in the polyphase motor only in primary copper loss, and the additional loss in the capacitor. The main phase loss will be the loss per phase in the polyphase motor.

$$\text{Main phase loss} = \frac{\text{polyphase loss}}{2}$$

$$\text{Capacitor phase loss} = i_{1s}^2 r_{1s}$$

Only the magnitude of current is of interest

$$\text{Capacitor phase loss} = \left(\frac{I_m}{K}\right)^2 r_{1s}$$

$$= \left(\frac{I_m^2}{K^2}\right) K K_a r_{1m} = (I_m^2 r_{1m}) \frac{K_a}{K}$$

$$\text{Total primary copper loss} = I_m^2 r_{1m}\left(1 + \frac{K_a}{K}\right)$$

$$= \frac{K + K_a}{2K} (\text{polyphase loss}) \qquad (18)$$

$$\text{Capacitor loss} = \frac{I_m^2}{K^2} R_c \qquad (19)$$

CONCLUSION

The method of designing capacitor motors given in this paper is briefly as follows:

1. Design the main winding to give the necessary maximum torque.
2. Calculate the performance as a two-phase motor with each phase like the main winding determined above.
3. Solve equation (**11**) for K.
4. Choose K_a to be as close to K as possible and solve again for K.
5. Solve equation (**12**) for X_c.
6. Design capacitor from X_c and correct above solutions if R_c is too far in error.
7. Calculate performance by equations (**15**), (**17**), (**18**) and (**19**).

As mentioned above, this method is useful only when the starting torque required is not too great.

In many cases, starting torque requirements determine the windings, and the motor must operate slightly unbalanced at full-load with the resultant circulating current and lowered efficiency. A sample calculation on a typical motor is given in the appendix.

LIST OF SYMBOLS

E_m = main winding and line voltage
E_s = capacitor winding voltage
E_c = capacitor voltage
e_{2m} = induced voltage in main winding
e_{2s} = induced voltage in capacitor winding
i_{1m} = primary current in main winding
i_{1s} = primary current in capacitor winding
I_M = current per phase in identical two-phase motor
I_L = line current of capacitor motor
A = power component of main winding primary current
B = reactive component of main winding primary current
J_m = current density in main winding
J_s = current density in capacitor winding
Wt_m = weight of wire in main winding
Wt_s = weight of wire in capacitor winding
$K = \dfrac{\text{effective conductors in capacitor winding}}{\text{effective conductors in main winding}}$
$K_a = \dfrac{\text{area of conductor in main winding}}{\text{area of conductor in capacitor winding}}$
r_{1m} = primary resistance of main winding
X_{1m} = primary reactance of main winding
Z_{1m} = primary impedance of main winding
r_{1s} = primary resistance of capacitor winding
X_{1s} = primary reactance of capacitor winding
Z_{1s} = primary impedance of capacitor winding
R_c = effective resistance of capacitor
X_c = effective reactance of capacitor (positive)
Z_c = effective impedance of capacitor
C = effective capacity of capacitor (in microfarads)

Appendix

Following is given an example of a capacitor motor design illustrating the method described in this paper. It is assumed that the main winding has been determined from the maximum torque requirements, and that the performance as a two-phase motor with each phase like the main winding has been calculated.

E_m = 110 volts (applied voltage)
r_{1m} = 1.89 ohms primary resistance of main phase
I_m = 2.39 amperes current per phase
Primary copper loss = 21.6 watts
Input = 273.6 watts
Output = 186.7 watts (1/4-hp., 110-volt, 60-cycle, two-phase, 4-pole)
Losses 86.9 watts
Efficiency 68.2 per cent
Power factor 52.0 per cent
R_c = 8.00 ohms
$I_m^2 = 5.7$
$A = I_m PF = 2.39 \cdot 52 = 1.24$
$B = \sqrt{I_m^2 - A^2} = 2.045$
K_a and K are assumed = 1.26

$$K = \frac{2.045 \times 110 - 1.26 \times 1.89 \times 5.7 - \dfrac{8.0}{1.26} \times 5.7}{1.24 \times 110 - 1.89 \times 5.7}$$

$$= \frac{225 - 13.57 - 36.2}{136.1 - 10.79} = \frac{175.2}{125.31} = 1.40$$

Second trial

$$K = \frac{225 - 13.57 - \dfrac{8.0\ 5.7}{1.42}}{125.31} = 1.430$$

$$X_c = \frac{1.43 \times 110 - 2.045 \times 8 - 1.43 \times 1.26 \times 2.045 \times 1.89 + 1.43 \times 2.045 \times 1.89}{1.240}$$

$$= 114.3 \text{ ohms}$$

$$C = \frac{2650}{114.3} = 23.2 \text{ effective microfarads}$$

$$I_L = \frac{2.39}{1.43}\sqrt{1.43^2 + 1} = 2.915 \text{ amperes}$$

$$\text{P. F.} = \frac{1.24 + \left(\dfrac{2.045}{1.43}\right)}{2.915} = 91.5 \text{ per cent}$$

$$\text{Primary loss} = \left(\frac{1.43 + 1.26}{2\ \ 1.43}\right) 21.6 = 20.3$$

(decrease of 1.30 watts)

$$\text{Capacitor loss} = \left[\frac{2.39}{1.43}\right]^2 8 = 22.4$$

Total losses 86.9 − 1.3 + 22.4 = 108.0

Output = 86.7

Input = 294.7

$$\text{Efficiency} = \frac{186.7}{294.7} = 63.3 \text{ per cent}$$

Fig. 2 is plotted from the values obtained in this example.

Discussion

L. A. Doggett: In this article as well as all previously published articles, the theory of the capacitor motor has been developed on the assumption of sine waves. The correctness of this assumption is challenged by the oscillogram of Fig. 1 which shows the current waves when a *RKS*-126, 2-hp., 1,800-r.p.m., 220-volt, 8.6-ampere, single-phase, 60-cycle, G. E. capacitor motor is operated from a practically sinusoidal source. (Analysis: $Y = \sin x + 0.01 \sin 2x + 0.00 \sin 3x + 0.01 \sin 4x + 0.01 \sin 5x$). These current waves are for the motor running light, curve $I_l = 4.4$ shows the line current; curve $I_c = 6.1$ shows the capacitor phase current; and curve $I_m = 2.4$ shows the main phase current

That these currents depart widely from sinusoidal shape throughout the whole range of operation is brought out by an I^2R, I^2X analysis of the load run test data. Since wattmeters measure the average power, not only of the fundamental but also of the harmonics, a reasonably close check was to be expected of the I^2R analysis. The I^2X values were calculated from the expression,

$$I^2X = (\overline{EI}^2 - [I^2R]^2)^{1/2}$$

which is true for sinusoidal cases only. The degree by which the I^2X analysis fails to check is a measure of the departure of the actual waves from sine waves. The wide discrepancies in the I^2X values, shown by Table I, indicate the presence of large harmonics.

So long as there is a transfer of power from one phase to the other there are bound to be large harmonics present. If the designs of Mr. Trickey avoid this transfer of power, oscillograms from motors of his design should show much better sine waves than those of Fig. 1. It is to be hoped that Mr. Trickey will submit oscillograms for some of his motors.

If there is a transfer of power, then one phase becomes a generator and the other phase becomes a receiver. It will hardly be claimed that such a generator is a sine-wave generator. To make matters worse, a sizeable condenser is included in the series circuit between the generator and the source. Thus the stage is set for the generation of harmonics, wide in variety and large in amplitude.

I^2R = wattmeter reading.

I^2Z = product of voltmeter and ammeter readings.

$-I^2X$ – condensive reactance volt amperes.

*The data of this table were prepared by A. R. Mengel and D. W. McGill, Enrolled Students A.I.E.E. at Pennsylvania State College.

C. G. Veinott: Anyone who has designed, or has attempted to design capacitor motors recognizes that the problem is tremendously involved and that there is a considerable number of factors which must be taken into account. Mr. Trickey's paper throws much useful light on this complicated problem in a simple manner. He shows the conditions which must be met in order to obtain operation equivalent to that of a two-phase motor and incidentally brings to light some interesting and important conclusions. For example, in Fig. 1, the winding ratio (ratio of capacitor phase turns to main phase turns) is of the order of the tangent of the power-factor angle of the motor when considered as a two-phase motor with both phases like the main winding. It is, therefore, necessary to have control of the winding ratio as well as the external microfarads in order to obtain balanced operation. This means that any polyphase motor cannot necessarily be operated as a polyphase motor from a single-phase source merely by the addition of a capacitor of suitable value in one phase. This fact seems to be often misunderstood by those not familiar with capacitor motors.

Fig. 1

P. H. Trickey: Regarding the advisability of operating a capacitor motor at its balanced operating point, Fig. 2 shows the effect of changing the voltamperes of the capacitor on efficiency, power factor, and apparent efficiency of a typical ¼-hp., 110-volt, 60-cycle motor. The balanced point is at *A*.

Having designed a motor for balanced operation, and calculated its performance by the method of this paper, the designer can choose actually to operate the motor at any value of capacitor voltamperes he wishes. Point *B* is the maximum efficiency point which will coincide with point *A* if $R_c = O$ and if $K = K_a$, point *C* gives the maximum power factor and point *D* gives the maximum apparent efficiency. The operator may operate at any one of these points, or if cost is of greatest importance the point *E* might be chosen, which gives a motor within 1½ per cent of the maximum efficiency and has only 59 per cent as many voltamperes. However, the power factor has dropped from 80 to 69 per cent.

If the designer chooses to operate at any point between *E* and *D*, this method is still of use to him in predetermining performance especially on new and radically different designs. Knowing the efficiency and power factor quite accurately at the balanced point, he can estimate very closely the performance at the actual operating point, from the general shape of the curves of Fig. 2.

In reply to Mr. Doggett's discussion the most prominent cause of harmonics in capacitor motor currents is saturation of iron, either in the motor itself or in the capacitor transformer. The transformer is the most likely cause because it has no air gap and on any voltage the magnetizing current may have a very bad third harmonic component. Unless a capacitor motor is returning power to the line through its main phase, the main phase current will have nearly the wave shape of the applied voltage except a slight distortion due to saturation in motor iron. The capacitor phase current will be distorted depending on the transformer saturation and since at no load the capacitor phase current is such a large proportion of the line current, the line current will also be distorted. The capacitor phase current will be symmetrical about a vertical axis, and since it adds approximately in quadrature to the main phase current, the line current will be distorted toward one side. Under no-load, overvoltage conditions this distortion may be very bad. In fact if the voltage is raised high enough, the capacitor phase fundamental magnetizing current will just balance the leading condenser current, and leave the third harmonic practically alone.

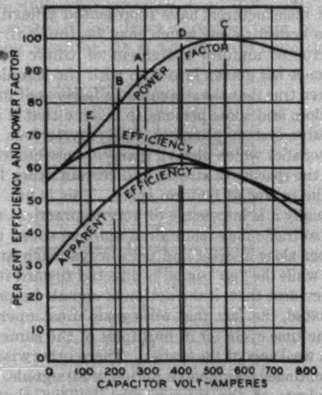

Fig. 2—Effect of Changing Capacitor Voltamperes on Capacitor Motor Performance

A. Balanced point
B. Maximum efficiency
C. Maximum power factor
D. Maximum apparent efficiency

However, I believe the wave shapes in a capacitor motor designed for balanced operation at full load, and with inductions sufficiently low in the transformer for operation at the usual overvoltages, will be close enough to a sine-wave for all practical purposes except at very light loads. At very light loads the motor is inherently unbalanced, and inefficient and a few harmonics more or less will not make it much worse.

The Flexible Progressive Traffic Signal System

BY H. I. TURNER*
Associate, A.I.E.E.

A FLEXIBLE progressive traffic signal system has been defined as one which provides a means of timing signals at different street intersections for operation in any desired relation with respect to each other, subject to the one limitation that the time of each cycle of operation must be the same at all intersections of the system. Such a range of adjustments usually makes it possible for an engineer to time the signals so that traffic may move east and west as well as north and south at certain predetermined uniform speeds without being obstructed by a "stop" signal after once having passed a "go" signal.

Most manufacturers have represented a flexible progressive system as one which may be timed to permit uninterrupted uniform movement of traffic after the traffic once has gotten into step with the signals. This is so often true that the statement is fairly well justified, but it does lead some persons to believe that a flexible progressive system possesses some mysterious timing characteristics which always make it possible,irrespective of the spacing of streets and certain other factors, for traffic to flow at uniform speed. This is not true as occasionally it is impossible or very impractical to time signals so traffic may maintain a uniform speed in both directions along a street and yet always reach an intersection while the "go" signal is directed toward it.

It is evident that, if the action of signals be properly coordinated, the fact that all signals must operate on the same time cycle (or in multiples of the same cycle) is not a weakness of the system. There otherwise could be no continued coordinated action of all signals. There are students of the subject who believe that it is theoretically impossible to provide any timing of signals within a given area which is an improvement over the timing that is possible in a genuine flexible progressive system, providing, of course, that facilities are furnished for readily varying timing to meet changes in conditions which develop during different times of the day. Some engineers believe that a single intersection, considered by itself, may often be dealt with more satisfactorily with signaling devices which are actuated by traffic than by any pretimed signals. A careful study of what can be accomplished by a properly-proportioned set timing of signals will, nevertheless, frequently indicate that even for many types of isolated intersections the controller with set timing deals with conditions as well or very nearly as well as the most elaborate system of traffic-actuated devices. Coordinated action of signals located at intersections of streets leading to a square having several entering streets is nearly always the most satisfactory way of dealing with these situations and the advantage of such a system becomes more evident as the volume of traffic entering the square increases.

In any event, traffic-actuated devices can rarely be introduced into the average flexible progressive system without upsetting the uniform flow of traffic to a more or less serious degree. In a great majority of congested districts the coordination of the movement of traffic through the entire district is of incomparably greater importance than the most efficient movement of traffic at any few intersections taken by themselves.

Signals may be timed for flexible progressive service by two general types of systems: *i. e.*, that which employs a central office type controller with no timing devices located at individual intersections, and that which employs a master controller at a central point and an individual controller at each intersection. A most outstanding example of the former is the controller which times the signals in the Chicago Loop District. Examples of the latter are found on Massachusetts Avenue, Cambridge; Olive Street, Saint Louis; Wilshire Boulevard, Los Angeles; Broad Street, Philadelphia, and in many other cities. All of these controllers have facilities for the following adjustments which entitle them to be classed as truly flexible progressive systems:

1. The time of each cycle of operation of the signals at any intersection may be adjusted from a central point. A cycle time anywhere between 30 and 120 seconds may be found useful in the average system.

2. The percentage of the cycle taken by the "go" signal and the "stop" signal may be adjusted over a wide range and adjustments made at one intersection are made independently of adjustments at any other intersections. In practise it has been found that ability to adjust both the "go" and "stop" periods from 15 to 85 per cent of the total cycle is all that is necessary.

3. The start of the cycle of operation of the signals at any intersection is 100 per cent adjustable with respect to the start of the cycle of operation of the signals at any other intersections of the system. The start of a cycle may be considered the instant when the "go" signal appears on any signal face and the total time of one cycle is the time which elapses between the appearance of one "go" signal and the appearance of the next "go" signal on the same face.

The chart A, Fig. 1, shows how it became necessary to time signals on one street to provide a progressive flow of traffic. The wide black marks indicate that traffic on the main street is facing a "stop" signal. At First Avenue a 25-second "stop" period for traffic on the main street was necessary. A 35-second "go" period was likewise necessary. In other words, during 58 per cent

---

*Eagle Signal Corporation, Moline, Ill.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

of the cycle the "go" signal shows to the main street. In order for traffic to flow in both directions without a stop, it was necessary for the signals at Second Avenue to show "go" to the main street during 75 per cent of the cycle. The adjustments necessary at the other avenues can be seen from the chart. These signals were so timed that traffic could start at either end of the street and proceed at 15 miles per hour past the other three intersections without being obstructed by a "stop" signal. A little study of the chart will make clear to the reader that traffic must not move much faster nor much more slowly than this speed or it will encounter a "stop" signal. This condition is one of the important features of a flexible progressive system—it discourages the movement of traffic at speeds either above or below that for which the system is timed.

Chart B shows what happens when the time of each cycle of the signals is changed from 60 seconds to 30 seconds. Traffic must now move 30 miles per hour to avoid "stop" signals instead of 15 miles per hour. The operator at the central station can, therefore, time the signals so as to discourage the movement of traffic at any speed other than the one he desires. No police officers on the street can so effectively control the speed of traffic as a well-engineered flexible progressive system. Traffic officers may restrict speed, but a flexible progressive system will actually make a driver try to hold his speed at that for which the signals are set. It is obvious that daily changes in traffic volume, slippery streets, and many other conditions which are constantly developing bring about excellent applications of the operator's ability to influence speed from a central point. Usually it has been found that a much larger volume of traffic can be handled by a comparatively low speed and systematic timing than by higher speeds without well-coordinated operation of signals.

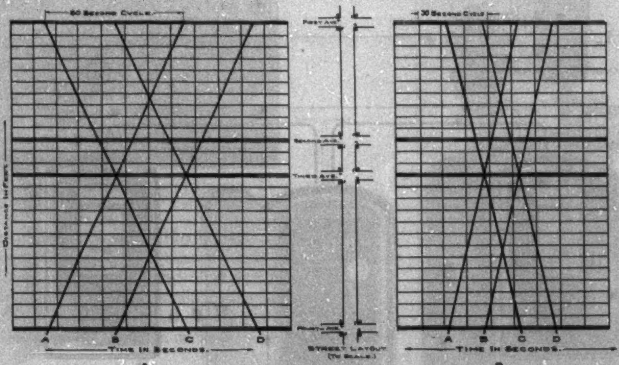

Fig. 1—Traffic Movement Chart

The following features or characteristics are important in any flexible progressive control devices:

1. Those which keep maintenance expenses and service interruptions at a minimum, such as: simplicity, sturdiness, smooth quiet operation, freedom from impact between parts.

2. Facilities for manual control. Usually the manual control of signals at one intersection of a system is objectionable because no officer can time the movements anywhere near as efficiently as can the controller itself. There are times when manual control is essential, however, such as immediately after an accident has occurred, when school children are leaving a nearby school and during times when very abnormal traffic conditions exist.

3. Facilities for shutting down the signals at each local controller and from a central point by merely throwing a switch. It is advisable to cause signals to flash amber lights when not operating as "stop" and "go" signals. Therefore, facilities should be provided at the central control point for causing signals to flash amber when not in normal operation.

4. Adjustments should be easily understood and of wide range. It is preferable that the controller be designed so adjustments may be made on a sliding scale and not in steps. A vehicle moving 30 miles per hour travels 44 feet per second and it is obvious that unless a controller can be adjusted to change its signals at the correct second it is not possible to handle traffic as smoothly as is possible when adjustments are set accurately as dictated by a traffic flow chart.

5. The duration of the amber light or warning that the signal is about to change should not increase as the total time cycle increases and should not decrease when the total time cycle is decreased. Fig. 1 shows that traffic has to travel faster when the time cycle is decreased in order to keep in step with the signals. If

decreasing the time cycle also decreases the amber or other warning signal, traffic, when it is traveling fast, receives less warning that it will be required to stop than when it is traveling more slowly. Obviously this is wrong. The amber period should either remain constant or else increase as traffic is speeded up and should either remain constant or decrease when traffic is slowed down. Any controller which causes its amber signal to increase or decrease as the total cycle increases or decreases will either provide too short an amber period at short cycles or too long an amber period at long cycles.

6. Means for exhibiting emergency signals by control from a central point. This usually consists of causing all signal faces to show red lights only and is for the benefit fo the fire department.

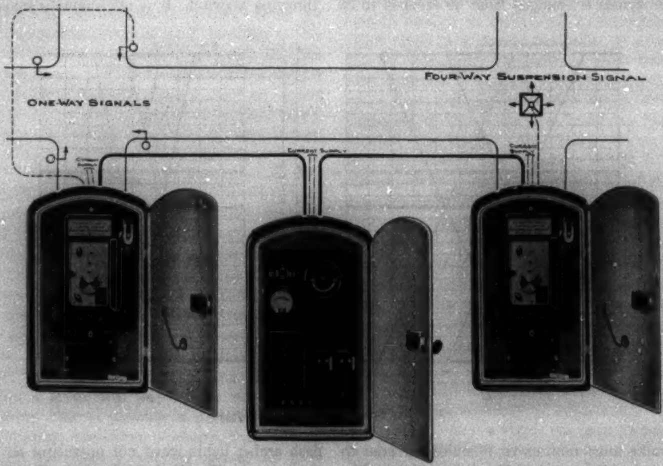

Fig. 2—Typical Master Controller Connected to Two Local Controllers

7. Means for aiding traffic movement during times of the day when traffic is very heavy on a particular street. Seldom does it happen that the ideal timing for conditions existing during most of the day is also ideal for peak hours. At such times facilities for increasing the "go" signals showing on the main thoroughfare or facilities for changing with respect to each other the times at which "go" signals at different intersections appear may meet the situation. If the "go" period is increased for the benefit of the main street, it gives cross street traffic less chance to move. If "go" signals at different intersections are shifted in time relation with respect to each other in order to favor traffic in one direction, whatever benefit is derived by traffic in that direction is at the expense of traffic in the other direction.

A description and brief history of two typical flexible progressive systems follow:

Chicago Loop System

This system was one of the earliest genuine flexible progressive systems to be placed into successful operation. It was so very substantially constructed that for six years it has functioned every day without an interruption worthy of mention. The flexible progressive system was installed in preference to other systems partly to minimize the peak load on the power station supplying power for the street railway system, as limited progressive and synchronized systems tend to make motormen start and stop many cars at the same instant at many street intersections.

From Fig. 3 the general construction of the controller is evident. It consists of individual units coupled together by a train of gears and driven by a motor. All of these units rotate at the same speed so that a complete cycle of signal changes at each intersection is accomplished in the same length of time irrespective of the relation of "go" periods to one another. Each dial shown in the illustration has associated with it four contacts, No. 3 closes circuit to north and south red lights and east and west green lights, No. 2 closes circuit to north and south green lights and east and west red lights. No. 1 and No. 4 close the circuit to amber lights in all four directions. The No. 3 contact and No. 2 contact are adjustable with respect to each other by arms in back of the dial, and by moving them to the proper positions, the red and green signals may be caused to show for any desired percentage of the cycle and the signals controlled by one unit may be caused to operate at any time with respect to the signals controlled by any other unit.

The total cycle may be increased or decreased by means of either one of two power units, each power unit consisting of a motor, an adjustable speed transmission and clutch which drive the entire train of gears. One advantage of the central office type controller is that as many and as wide variations in timing of signals as may be required to meet variations in traffic conditions during the day may quickly be effected by the operator in charge. The controller is located near the central point of the Chicago Loop District and all power for the lights is conducted over wires issuing from this central office. This system is probably the most sturdy and simplest flexible progressive system in existence.

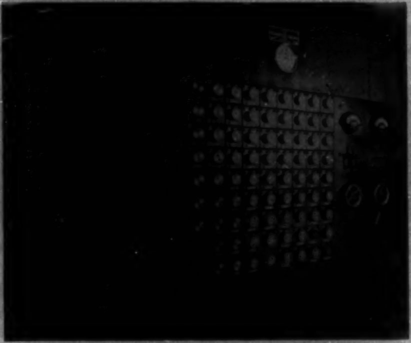

FIG. 3—CENTRAL OFFICE TYPE CONTROLLER OF CHICAGO LOOP SYSTEM

WILSHIRE BOULEVARD, LOS ANGELES, CALIFORNIA

The flexible progressive system was specified for Wilshire Boulevard only after a long and intensive study. It has been stated that both the density and speed of traffic on this thoroughfare are higher than on any other avenue in the country. In any event, Los Angeles claims more automobiles in proportion to its population than any other large American city and this is reflected in an unusual traffic problem on Wilshire Boulevard.

Wilshire Boulevard uses the Coordiplex system. This system employs at each intersection controllers having two induction disk motors. One of these motors drives a cam shaft intermittently and its rotation causes the lights to change from "stop" signal to "go" signal or vice versa. The other motor called the "cycle motor" closes the contacts which start the first motor when it is time for signal lights to change. The cycle time is controlled by a master timer located at a central point. Once during every cycle of operation of the lights, all cycle motors are brought to a stop for about one second and by means of an impulse sent out from the master timer are caused to start into motion at the same instant. Errors in the speed of these motors are thereby cancelled by the beginning of each cycle of operation. The speed of these motors as well as the speed of the master timer which sends out the re-synchronizing impulse is varied by the voltage impressed on the system by an adjustable voltage auto-transformer located at the master switchboard. This system provides flexible progressive operation in its strictest sense. The time of the "go" and "stop" periods, also the timing of one controller with respect to others is set by self-locking arms on the cycle motor dial of each intersection controller. The system enables an operator instantly to cause all signals to show red lights for the benefit of the fire department. It may be operated at late hours of the night with flashing amber showing on Wilshire Boulevard and flashing red showing on the cross street. Amber lights preceding the color change may be set at any desired interval, but when once set the interval does not vary when the cycle time is changed at the master controller. All controllers may be operated manually and one position on the manual control provides for red lights in all directions at the intersection under manual control.

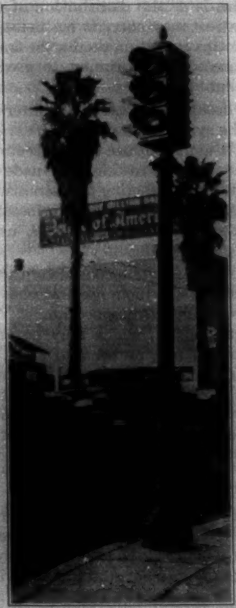

FIG. 4—WILSHIRE BOULEVARD SIGNAL

The Electro-Matic Traffic Dispatching System

BY H. A. HAUGH, Jr.*
Associate, A.I.E.E.

THE electro-matic vehicle-actuated traffic-dispatching system, as its name implies, is a system of traffic control by which the traffic in a given area controls itself. In its operation it approaches the ideal system in which the right-of-way or "green light" period is assigned to the approaches to an intersection in proportion to the volume of traffic on each approach. For example, if at the junction of A and B streets there is twice as much traffic on A street as on B street, the timing of the traffic-light cycle will be so adjusted that, within certain limits, the A street green light period will be twice as long as the B street green light period. A few minutes later the distribution of traffic may be reversed. B street may carry twice as much traffic as A street. When this condition occurs the traffic light cycle will be readjusted in its timing to give B street the longer green light period.

Originally designed for use at the intersection of only two streets the system has since been expanded and improved until it is now in use at intersections where five or six streets meet. Provision is made for handling trolley cars and for protecting pedestrians. Under traffic conditions varying from instant to instant it operates to produce a smooth flow of vehicles, using the intersection at its greatest efficiency.

The electro-matic system consists of three parts:

1. The detectors, which are switches operated by vehicles approaching the intersection.
2. The signal lights, which may be any one of the standard types of red, amber and green traffic lights. The amber light may be eliminated if so desired.
3. The dispatcher, which receives electrical impulses from the vehicle detectors and controls the signal lights in accordance with the traffic requirements as indicated by the detector impulses from all streets.

THE DETECTOR

The detector may be any one of several types such as a mechanical switch, an electromagnetic unit, or a beam of light which will be interrupted by approaching vehicles. Experiments have been made with all of these types of vehicle detectors and all of them are now in use in electro-matic systems.

The mechanical type of detector is the simplest, cheapest and the most practical. The mechanical detector used in this system consists of a pair of thin flexible steel plates separated by a strip of rubber around the edge which holds them normally one-quarter of an inch apart. The passage of a vehicle over the detector flexes the upper plate so that it makes contact with the lower plate thereby causing a current to flow to the dispatcher. These steel plates are completely enclosed in a rubber package which is vulcanized to them, thus making the whole a water-tight unit. A lead wire is attached to each plate and brought out from the package through a rubber pig tail. Fig. 1 is an illustration of a detector package. The detector package is laid in an iron casting, a strip of rubber one-half inch thick is bolted over the top of this casting to protect the package from mechanical damage by the cars which cross it, and the casting is ready to be placed in the street for service. At one end of the iron casting is a junction box in which the wires running to the dispatcher are connected by a water-tight joint to the leads from the detector package. This construction gives an extremely simple detector unit absolutely water-tight and thoroughly reliable (there are no levers, pinions, or bearings to wear or get out of order). Operating with an electro-matic dispatcher this type of detector will "pick up" a vehicle traveling at sixty miles an hour. Fig. 2 shows a mechanical detector imbedded in the pavement.

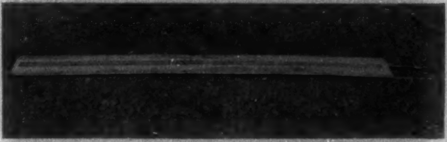

FIG. 1—A DETECTOR PACKAGE

FIG. 2—A DETECTOR IMBEDDED IN THE PAVEMENT

The casting which holds the detector package is twelve inches wide, two inches deep and is made in three lengths, four, six, and eight feet. The shortest is used between the rails of a trolley track and the other two sizes are used to "cover" streets of different widths. In "covering" the side of a street on which vehicles approach an intersection it is not necessary to place the detectors immediately adjacent to each other. If the street is wide enough to require two or more detectors they are located along a line at right angles to the curb and are spaced four feet apart end to end. Since the

---

*Vice President, Automatic Signal Corp., New Haven, Conn.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

tread of a standard vehicle is more than four feet, one wheel is bound to cross one of the detectors thus sending an impulse to the dispatcher. If a vehicle crosses the detector in such a way as to send in several impulses some caused by the front wheels and some by the rear wheels, the operation of the system is not impaired.

Occasionally a street will be so narrow that vehicles going in either direction must perforce travel the middle of the highway. To prevent the sending of impulses by vehicles leaving such an intersection a special "directional" detector is used. The directional detector sends an impulse to the dispatcher from those vehicles approaching the intersection but does not send any impulse when crossed by a vehicle leaving the intersection. This effect is accomplished by splitting the top steel plate lengthwise and bringing out three leads from the detector package instead of the usual two. One of these leads is attached to each half of the top plate and the third is attached to the single bottom plate. By longitudinally splitting and electrically separating the top plate into the two parts, one on each side of the center line of the detector package, two impulses are sent to the dispatcher by each vehicle crossing the detector. Calling these impulses *A* and *B* it is evident that a vehicle crossing the detector will send in the two impulses, one shortly after the other. If a car moving toward the intersection sends the impulses in the order *A* followed by *B*, a car moving away from the intersection will send them in the reverse order, *B* followed by *A*. A relay system is arranged to pass on to the dispatcher the impulse *A* followed by *B* but it will stop that of *B* followed by *A*. Thus the directional effect is achieved.

THE DISPATCHER

The outstanding characteristic of the electro-matic system is its extreme flexibility. The timing of the signal light cycle is constantly changing to meet the irregular demands of traffic. The secret of this flexibility is to be found in the dispatcher, which is essentially a group of time-delayed relays combined with a switching mechanism. The switching mechanism operates the traffic signal lights. It receives and stores until used all impulses sent from the vehicle detectors. It also switches the group of time-delayed relays and vehicle detectors into different parts of the circuit as the green light is shifted from street to street. The time-delayed relays act as watchmen who keep an eye on each street while it has the green light, to see that it does not hold the right-of-way longer than is necessary. These "watchmen" will go so far as to stop a line of moving cars, when occasion requires, in order to give traffic on a cross street a chance to move. The functioning of these relays is worthy of some consideration.

There are three time-delayed relays in this group. One of them measures the amber light period and the "initial period" which will be discussed later in this paper. The operation of the second of these relays (called the vehicle interval relay) signifies that a line of cars has completely passed the intersection and puts the system into such a condition that a "call" from the cross street will cause immediate transfer of the right-of-way thereto. This transfer, however, takes place only when cross traffic "requests" it.

The operation of the third time-delayed relay (called the maximum-interval relay) signifies that a car has been kept waiting on the cross street for a period of time sufficiently long to warrant arbitrarily stopping the moving traffic to let it move into the intersection. When the maximum-interval relay operates it produces an effect beyond that of the vehicle-interval relay. The vehicle-interval relay merely makes the right-of-way subject to call by cross-street traffic. The maximum-interval relay, on the other hand, causes immediate transfer of the right-of-way to the cross street.

The vehicle-interval relay serves to protect a moving line of cars against unwarranted interruption by cross traffic. The maximum-interval relay serves to protect waiting cross traffic against being unreasonably delayed by a "solid" line of moving cars.

As might be expected from the difference in their functions these two relays are energized through separate circuits. The vehicle interval relay is energized through a rather peculiar connection in order to permit a "solid" line of moving cars to protect its right-of-way by preventing this relay from operating. As each street is given the green light the vehicle detectors located in that street are connected by the dispatcher switching mechanism to the vehicle-interval relay in such a way that impulses from these detectors will reset this relay. Hence the vehicle-interval relay will not operate to yield the right-of-way to cross traffic so long as cars coming into the green light continue to reset it by operating the detectors at short intervals. A break in the line of moving cars will, however, give the vehicle-interval relay time to operate and put the system into a condition to respond immediately to "calls" from cross-street traffic. Whenever the intersection is free of moving traffic this relay causes the right-of-way to be subject to call by cars on the cross street. But, on the other hand, it will not operate and therefore will not release the right-of-way to cross traffic so long as cars continue to move through the intersection.

The maximum-interval relay is energized as soon as a car has indicated its presence on the cross street by operating the cross-street detector. This relay is not reset by moving cars. Therefore, if at the end of a predetermined period subsequent to the arrival of cross traffic, there has been no break in the moving traffic, the maximum period relay will operate to transfer the right-of-way to the waiting cross traffic.

It can be seen that the vehicle-interval relay and the maximum-interval relay working together cause the right-of-way to be yielded to cross-street traffic when the intersection is clear, or even when it is not clear if the cross traffic has waited for a predetermined period, but they never interrupt moving traffic unless the right-of-way has been called to the cross street by waiting traffic or a "pedestrian period."

TIME INTERVALS

The time intervals measured by this group of time-delayed relays are basic units in the electro-matic system and may be described as follows:

1. The *amber interval,* the period during which the amber light is shown.
2. The *vehicle interval,* the time required for a single vehicle in motion to pass through the intersection.
3. The *initial interval,* an additional interval inserted at the beginning of each green light period in order to give those cars which are not in motion a little extra time to get under way.
4. The *maximum interval,* the time during which the traffic in one street can hold the right-of-way against waiting cross traffic.

The vehicle interval is such an important unit in the electro-matic system that it merits more detailed consideration.

It is measured by the vehicle-interval relay and is the means by which moving cars can extend the right-of-way period between the minimum limit (set by the initial interval plus one vehicle interval) and the maximum limit fixed by the maximum interval. Each car which crosses the detector in the street which has the right-of-way cancels, by resetting the vehicle interval relay, the remainder of the vehicle interval allotted to the preceding car and starts a new vehicle interval to hold the green light while it passes through the intersection. The cancellation of the remainder of each vehicle interval by the succeeding vehicle is a very important factor in providing for the highest efficiency in the use of the intersection. In operation, this cancellation means that the cross traffic does not have to wait for a series of accumulative vehicle intervals to expire. Right-of-way will be transferred to the waiting cross traffic immediately after the last car of a moving line has passed through the intersection.

To demonstrate how these time intervals are used to produce a smooth flow of traffic assume four different traffic conditions at the intersection of A street and B street. These traffic conditions may be designated as cases 1, 2, 3, and 4, described as follows:

1. Cars moving on A street with no traffic on B street.
2. Cars moving on A street with one car waiting on B street.
3. Cars moving on A street with several cars waiting on B street.
4. Heavy traffic on both A street and B street.

In case 1, the cars on A street have the right-of-way and there is no waiting traffic on B street. The maximum interval is not being measured since no B street traffic has called for the right-of-way. The initial interval has expired. The vehicle interval is being intermittently renewed through the resetting of the vehicle interval relay by the cars crossing the detectors on A street. The vehicle interval relay is operating from time to time. However, since the right-of-way has not been called to B street, the operation of the vehicle interval relay does not act to transfer the right-of-way thereto, the green light continues to shine on A street and A street traffic flows without interruption.

In case 2 traffic is moving out of A street and a single car is waiting on B street. The A street initial interval has expired. Let us assume that the cars on A street are crossing the detectors at sufficiently short intervals to reset invariably the vehicle interval relay before it can operate. The vehicle interval relay therefore tends to hold the right of way on A street. However, the A street maximum interval is being measured because the car in B street, when it crossed the B street detector, energized the maximum interval relay. The transfer of the right-of-way to B street will be made in this case when the A street maximum interval has expired. If, on the other hand, we assume that the cars on A street are "straggling" or that the A street line of traffic completely passes the intersection before the maximum interval expires, the right-of-way will be yielded by the operation of the vehicle interval relay as soon as the A street traffic breaks. It can be seen that, with waiting cross traffic, the vehicle-interval and the maximum-interval relay are both energized, the right-of-way being yielded by the first to operate. Inasmuch as in this case there is only one car on B street, the green light will revert to A street by action of the vehicle-interval relay, after the initial interval and one vehicle interval have elapsed.

In case 3 the right-of-way will be transferred to B street exactly as in case 2. The instant that the B street green light is illuminated the timing of the initial interval begins. This will be succeeded by the first vehicle interval. However, in this case there are several cars waiting on B street. Before the end of the first B street vehicle interval this line of cars will be in motion and will be crossing the B street detector thereby always resetting the vehicle interval relay each time before it has time to operate. These cars will therefore hold the right-of-way on B street until they have had sufficient time to pass through the intersection, the time being assumed to be less than the maximum interval allowed for B street traffic against waiting A street traffic. As the last B street car passes the intersection the right-of-way will be transferred to A street by the operation of the vehicle interval relay.

In case 4 where traffic was assumed to be heavy on each street, the vehicle interval relay will be repeatedly reset by successive cars thereby holding the right-of-way on each street until the operation of the maximum relay yields it. It is surprising how seldom this condition occurs even when traffic seems to be very heavy. Interruptions constantly occur in the flow of traffic. A trolley or a bus must, in providing the public with adequate service, stop at any street corner when passengers require it. The electro-matic system permits cross traffic to take advantage of all such breaks in the moving traffic.

The electro-matic dispatcher has been described in some detail from a functional standpoint. A short description of its actual makeup may prove interesting. Fig. 3 is a front view of a dispatcher. The dispatcher was described earlier in this paper as a combination of a switching mechanism with a group of time-delayed relays. The switching mechanism consists of a shaft on which are fixed several cams and a separate group of contacts which are either opened or closed by the action of these cams. A cam shaft with some associated contacts is shown in Fig. 4. In completing one signal cycle this cam shaft makes one revolution. It is operated by a solenoid-actuated ratchet and pawl, Fig. 5, which turns it through an angle of 60 deg. at a time. The solenoid which drives the cam shaft is in turn controlled by the time-delayed relays. Hence, when the time-delayed relays say in effect that traffic conditions warrant it, the solenoid advances the cam shaft into its next position thereby also advancing the signal lights one step in their cycle. In addition, as stated before, the vehicle detectors and the time-delayed relays are by this act switched into the particular place in the circuit which they should occupy during this step of the traffic signal cycle. Presently the time-delayed relays will again act to advance the cam shaft into its next position thereby advancing the system one more step in its cycle. Six such steps constitute a complete cycle which is repeated as often as traffic conditions may require it. In following the operation of the cam shaft through one cycle assume a standard red, amber and green color cycle with amber displayed on both streets between the red and the green periods.

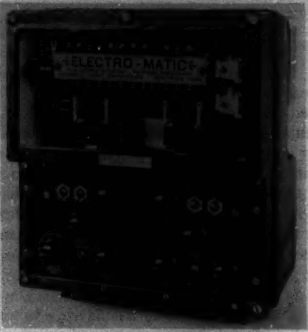

Fig. 3—The Front View of a Dispatcher

In each cam-shaft position one of the time intervals upon which the electro-matic system is based is being measured to determine when to move the shaft into its next position. Again referring to two intersecting streets as A and B streets, let us designate as position 1 the position which the cam shaft holds when A street has just been given the right-of-way. The shaft remains in position 1 during the A street initial interval. The time-delayed relay measuring this interval is energized continuously while the cam shaft is in position 1. To end this period the initial-interval relay operates the solenoid to move the cam shaft into position 2. No change in the signal lights accompanies the change from position 1 to 2. Position 2 might aptly be called a waiting position. The cam shaft does not move again until traffic requires the right-of-way to be shifted to B street. While the shaft is in position 2 the vehicle interval relay is energized and if there is waiting cross traffic the maximum interval relay is also energized. When the right-of-way is to be transferred to B street either the vehicle-interval relay or the maximum-interval relay will cause the solenoid to move the cam shaft into position 3. In this position the cam contacts close the circuit to the amber lights, energize the amber interval relay and open the circuits feeding all red or green lights. At the end of this period the amber interval relay operates to cause the solenoid to advance the cam shaft to position 4. Positions 4, 5, and 6, correspond respectively to positions 1, 2, and 3. Inasmuch as the latter three positions differ from the former only in that the right-of-way is being transferred to A street instead of to B street, there is no need to follow this operation through positions 4, 5 and 6.

THE TIMING UNITS

It is desirable that each of the four basic time intervals of the electro-matic system should be variable in magnitude as they are applied to traffic in different streets. A slight grade on one approach may cause cars entering the intersection from that street to be somewhat slower in starting than those on the cross street. To compensate properly the initial interval and perhaps the vehicle interval on the "slow" street should be somewhat longer than the corresponding intervals on the other. Or it may be desirable to allow a longer maximum period for one street than for the other. "Static timing" as used in the electro-matic system greatly facilitates such variations.

The static timing unit (the type of time-delayed relay now used in the electro-matic system) consists of a Strowger relay, a condenser, a resistance unit and a grid-glow flashover tube. The timing is actually accomplished by applying the well-known fact that the period required to charge a condenser to a given potential, under a uniform impressed e.m.f., depends upon the magnitude of the resistance in series with the condenser. The grid-glow tube is shunted across the condenser through the coil of the Strowger relay. When the condenser voltage reaches the critical voltage of the tube the tube "breaks down" and becomes a conductor. This permits the energy stored in the condenser to discharge through the relay coil which causes the relay to operate, thus signifying that the interval being measured has expired. As this timing unit is switched from place to place in the circuit, the charging resistance in series with the condenser is changed to meet the different timing requirements. Thus, for instance, the vehicle-interval timing unit, which serves each street in turn, may be set for a five second period on one street, whereas on another street it may operate after eight seconds. In a like manner the initial- and the maximum-interval relays can be used to time their particular intervals for one street after another, giving a different period for corresponding intervals on each street. The parts of these timing units are so located in the dispatcher that no photograph can include them all. Three condensers, one for each timing unit, with their associated Strowger relays may be seen in Fig. 6.

The important function of resetting the vehicle-interval relay is accomplished by discharging the condenser in this timing unit by action of a vehicle-detector relay.

Each timing interval, the initial, the vehicle, the maximum and the amber interval is independently adjustable for each street. This adjustment is made by turning a knob on a panel until the arrow thereon points to the number of seconds desired for the particular interval controlled by that knob. As a knob is turned it introduces resistances of different magnitudes into the condenser charging circuit which it controls thereby changing the time required to charge the condenser to the critical voltage of the grid-glow tube.

FIG. 8—PRESENT TRAFFIC FLOWS EXCHANGE PLACE

This paper describes a standard two-phase system which provides complete vehicle actuation for signals governing two interfering lines of traffic. By using a somewhat more complicated switching mechanism in conjunction with the three basic timing units the system has been adapted to control traffic at intersections where as many as six or seven interfering flows cross. Furthermore, adjacent intersections may be interconnected so as to operate with a certain degree of coordination without unduly interfering with the free vehicle actuation of each. Exchange Place in the center of Providence, Rhode Island, provides a good example of this type of installation. The location of vehicle detectors and signal lights is shown in Fig. 7. The various traffic flows are shown in Fig. 8, a study of which shows that there are several one way streets.

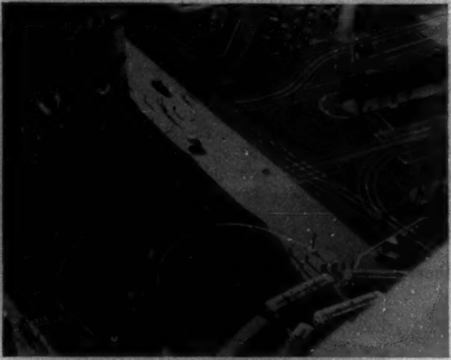

Fig. 9—Exchange Place Showing Trolley Loading Station

The traffic in each corner of Exchange Place is controlled by a separate independent vehicle-actuated dispatcher which gives the right-of-way in general to north-south traffic and to east-west traffic independently in order to eliminate crossing flows. The right turn traffic out of Washington Street, that from the southern end of Exchange Place into Fulton Street, and that out of Dorrance Street South, as well as the left turn traffic around the central section, moves at all times except during pedestrian protection periods. Pedestrians are a major factor in Exchange Place traffic. A trolley loading station located in the southern end of the Place, shown in Fig. 9, makes it necessary for thousands of people to cross the streets clustered about this point. To give these people a maximum of protection with a minimum of inconvenience to the motorists a "progressive" pedestrian period is provided. This period is inaugurated by showing the red light on all streets at the southwest corner, thereby stopping all traffic inbound to the southern end of Exchange Place. At the same instant the dispatcher controlling the traffic at the southeast corner begins to limit signal changes there in order to be ready for its pedestrian period which will commence 15 seconds later. This 15 seconds between the inception of the pedestrian periods at the two corners permits cars which were already in the southern end of Exchange Place when the pedestrian period was started at the southwest corner to pass out of this district without being stopped at the southeast corner. Hence the whole southern end of Exchange Place is cleared of traffic to give the pedestrians unhampered use of this district. At the termination of the pedestrian period traffic is first allowed to move at the southwest corner. A few seconds later, just as the first cars moving through the southern end reach the southeast corner, the pedestrian period is ended there and traffic again flows smoothly.

A Recent Development in Traffic Control

BY H. W. VICKERY* and V. W. LEONARD*
Non-member Non-member

***Synopsis.**—The large number of automobiles in use today has introduced new problems in the control of vehicular traffic. Timing devices with increased flexibility are required so that signals can be operated more nearly in accordance with varying conditions of traffic flow. A recently developed timing device, containing new features and having increased flexibility, offers a solution of the problems involved. The timer is described and its advantageous features are discussed.*

INTRODUCTION

CONGESTED traffic conditions of the present day indicate the necessity for greater flexibility in timing apparatus so that signals can be set in step with traffic and adjusted to accommodate variations in traffic flow. Rapidly changing traffic conditions emphasize the need for timing devices capable of adjustment to meet future requirements. As a solution of these problems, a timing device, with new characteristics and extremely wide ranges of adjustment, has recently been developed.

TYPES OF TRAFFIC CONTROL SYSTEMS IN USE

Traffic control systems now in use are of the following general types: first, the isolated system for controlling traffic at a single intersection; second, the non-interconnected progressive system in which timing devices at various intersections, though not interconnected in any way, can be adjusted to operate the signals in a progressive relation; and third, the interconnected progressive system in which not only a progressive relation of the signals is maintained but, in addition, certain features are obtained by remote control, such as change of total time cycle, selection of various progressive relationships, shut down, flashing amber and fire control.

A fourth type of interconnected system is that in which timing apparatus at the central point alone controls signals at a number of intersections. One form, in which a single timer controls the system, is extremely limited as far as flexibility is concerned. In its other form, where a timer for each intersection is located at the central point, the installation cost is so high as almost always to be prohibitive.

The discussion, therefore, is confined to the first three systems mentioned, in which individual timing devices are located at each intersection.

ADVANTAGES OF SYNCHRONOUS MOTOR DRIVE

Timing devices in non-interconnected progressive systems must, of necessity, be driven by synchronous motors in order that the progressive relation between intersections be maintained.

The advantages of synchronous motor drive in isolated and in interconnected progressive systems are brought out by consideration of a practical form of timing device. Such a device is shown in Fig. 1.

The synchronous motor (Fig. 2) operates on the hysteresis principle. Thus, unusual torque is developed with the expenditure of a small amount of power. The rotor is unconventional in the fact that it simply consists of hardened steel laminations spun into a drawn brass shell. All windings are stationary, surrounded and protected by the rotor. This construction produces a sturdy motor unit, insusceptible to damage in operation or handling as opposed to the inherently frail disk type of motor commonly used.

Any setting which may be made on a synchronous timer, whether it be total time cycle, proportion of periods in the color sequence, or progression setting is exact. All dials are marked in exact values due to the fact that the speed of a synchronous motor is independent of voltage, temperature and even fairly wide friction changes.

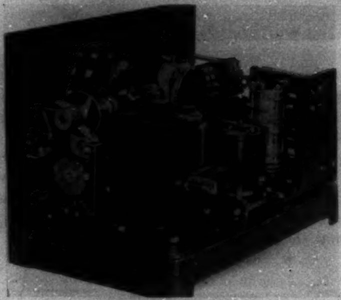

FIG. 1—REAR VIEW OF SYNCHRONOUS TIMER WITH COVER REMOVED

Any setting which may be made on an induction timer, on the other hand, is inexact. The total cycle dial must be calibrated, that is, various total cycles must be measured by means of a stop watch or some other standard and the dial marked to correspond. Changes in temperature, voltage or friction render such dial markings inaccurate.

Induction timers in interconnected systems require a compensating period, which is introduced once each

---

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

cycle, to correct for the inaccuracies in speed of the various timer motors. The master controller is set to operate at a time cycle slightly longer than that of the intersection timers. The intersection timers complete one total cycle at which time they stop and wait for the master controller to overtake and release them.

Synchronous timers in interconnected systems, on the other hand, due to their time keeping accuracy, require no waiting or compensating period. A short resynchronizing interval is provided once each cycle, simply as a supervisory check, so that any timer which may be out of step, due to servicing, tampering or other reasons, will immediately be placed back in step. The master controller is merely a supervisory device, whose function is not to keep the timers in step, but simply to place them in step.

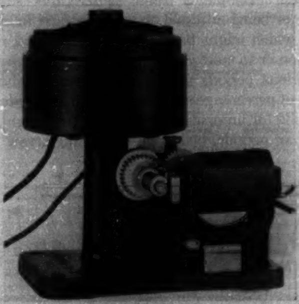

FIG. 2—SYNCHRONOUS MOTOR UNIT

While it is true that interconnected induction timer systems, in some cases, continue to operate even though central power fails, they usually speed up in case of such failure and, due to their non-synchronous principle, are no longer able to maintain progressive relationship. The interconnected synchronous timer system, on the other hand, not only continues to operate when central power fails but, due to its synchronous principle, maintains the same total cycle, the same progressive relationship and the same percentage values as before.

Another advantage of synchronous motor drive is the fact that flashing signal lights can be made to operate at a given, constant and exact speed, regardless of any change in total cycle which may be made. Such operation is not possible with an induction timer because in such case, the rate of flashing changes in proportion to the total cycle.

CHANGE OF TOTAL TIME CYCLE

The gear shift unit used for changing the total time cycle is shown in Fig. 3. It consists of a cone of gears of varying diameters and an idler gear which can be shifted to engage any one of the cone gears. The gears can be shifted manually at each timer or, in the case of interconnected systems, from a remote point. The total cycle range is flexible, usually consisting of ten steps with five seconds between steps.

While it is true that an induction timer, in which the total time cycle is usually changed by varying the motor speed, can apparently be set in steps much smaller than five seconds, it is probable that, due to voltage, temperature and friction changes, the actual total time cycle varies as much if not more than five seconds from the time cycle indicated on the dial.

SELECTION OF PROGRESSIVE RELATIONSHIPS

In order that traffic may move along a street at a given uniform speed and with a minimum number of stops, it is necessary that the signals be set in step so that traffic arrives at each intersection during the green or "go" indication. Setting the signals in step gives a progressive movement to traffic, the traffic moving in groups or platoons along the street.

To give ideal progressive movement to traffic in a given direction, it is necessary that the beginnings of the green indications of the signals occur successively one after the other in the given direction, the time elapsing between the beginning of the green indication of any one signal and the beginning of the green indication of the next adjacent signal in the given direction being equal to the time required to travel the distance between the two signals at the given speed.

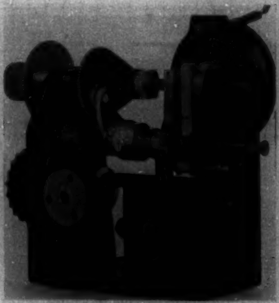

FIG. 3—GEAR SHIFT UNIT

Unfortunately, due to unequal distances between signals and due to the particular speed at which it is desired to have traffic move, setting the signals in step to give ideal progression in one direction usually results in very poor progression in the opposite direction (Figs. 4 and 5). The beginnings of the green indications of the signal, almost invariably, do not occur in a sequence in the opposite direction to allow as large a number of automobiles to travel without stopping, as is possible in the direction of ideal progression.

The usual procedure, where only one progressive relation of the signals is available, is to set the signals in step so as to give average progression in both directions (Fig. 6). With average progression, however, the number of automobiles which can travel in either direction without stopping is smaller than would be possible in the direction of ideal progression as shown in Figs. 4 and 5. Furthermore, continual stopping and starting of some of the traffic, due to the beginnings of the green indications of the signals being out of step, creates confusion and delay, thereby diminishing the number of automobiles which otherwise would be able to proceed without stopping.

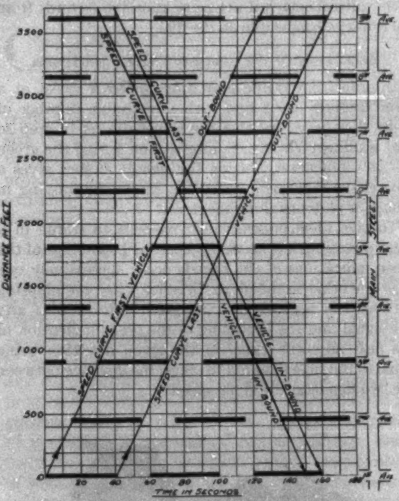

Fig. 4—Schematic Timing Diagram Showing Ideal Progressive Relation Favoring Out-Bound Traffic

Traffic speed—20 miles per hour. Total time cycle—60 seconds
Main street "green"—40 seconds indicated by heavy lines

Since, in large urban districts, traffic on a given street may be mostly inbound in the morning, mostly outbound in the later afternoon, and about equally divided in both directions at other hours of the day and since the volume of traffic in such districts is usually much greater during the morning and late afternoon than at other hours of the day, it is obvious that a single progressive relation of the signals does not meet these three fundamental traffic conditions in the best manner possible. A means, therefore, has been developed in the timer to give three separate and distinct progressive relations of the signals. Thereby, the progressive relation can be changed remotely to give ideal progression to inbound traffic in the morning, ideal progression to outbound traffic in the late afternoon and average progression in both directions at other hours of the day.

Adjustment Flexibilities

Since traffic conditions change from month to month and from year to year, sufficient flexibility should be built into traffic signal timing apparatus to insure that such apparatus shall not shortly become obsolete. In other words, a traffic signal timer should have sufficient flexibility to allow of adjustment to meet changing and, as far as possible, new requirements which may develop. For example, a traffic signal timer should be capable of being adjusted to meet changes in color sequence which might be authorized by federal or state legislation or to meet certain special local requirements. The various periods of the color sequence should be capable of percentage adjustment over very wide ranges to provide for unforseen conditions which might occur. Pedestrian periods, bell or green turning arrow indications which might later be required should be easily obtained by minor changes in the timer as opposed to intricate relay combinations used at present to secure such features.

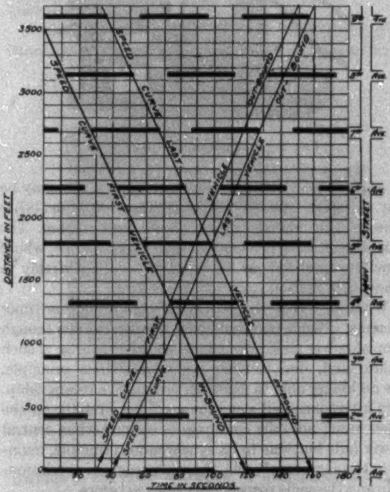

Fig. 5—Schematic Timing Diagram Showing Ideal Progressive Relation Favoring In-Bound Traffic

Traffic speed—20 miles per hour. Total time cycle—60 seconds
Main street "green"—40 seconds indicated by heavy lines

A solution of these problems is represented by a drum unit (Fig. 7), a rotating switch attached to the gear shift unit in Fig. 3 and a cycle percentage dial having 100 slots and containing a predetermined arrangement of easily removable keys as shown on the timer panel in Fig. 8. The drum contains a predetermined arrangement of cams for opening and closing the signal light contacts and is rotated in steps by means of a solenoid-operated ratchet. As the finger of the rotating switch strikes a key in the cycle percentage dial, contact is momentarily made and an impulse applied to the operating solenoid of the drum, thus causing the drum to advance to a new position or period in the color sequence.

Extreme flexibility is obtained by such construction inasmuch as any of the modern color sequences can be obtained merely by setting up the proper arrangement of cams on the drum. Also, any desired percentage adjustments of the periods in the color sequence can be obtained simply by proper arrangement of the keys in the cycle percentage dial.

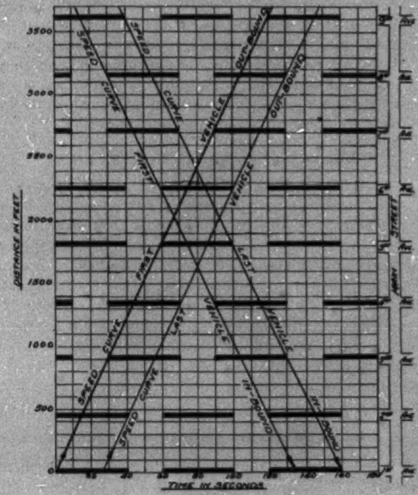

Fig. 6—Schematic Timing Diagram Showing Progressive Relation for Average Traffic Flow

Traffic speed—20 miles per hour. Total time cycle—60 seconds
Main street "green"—40 seconds indicated by heavy lines

The drum unit is mechanically independent of the cycle percentage dial as opposed to conventional construction in which fanned cams are used, not only to determine the length of each color period, but, by means of drops in these cams, to change the lights from one condition to another. Such fanned cam construction is usually limited as far as changes in color sequence or percentage adjustment of color periods is concerned.

A unique feature of the cycle percentage dial is the fact that there are no moving parts on the front of the timer and yet direct visual indication is given at all times, not only of the relative length of each color period, but also of the position of each period in the color sequence. This is not true of fanned cam construction since, to obtain the length of the cross-street green period, it is necessary to subtract the sum of all of the other periods from 100 per cent. Furthermore, with such construction, no indication whatever is given of the positions of the periods in the color sequence. Also, in some cases, the existence of certain auxiliary periods, such as warning periods, pedestrian periods, or bell periods, is not indicated at all on the front of the timer, inasmuch as such periods are usually obtained by the internal adjustment of slotted cam sectors inside the timer.

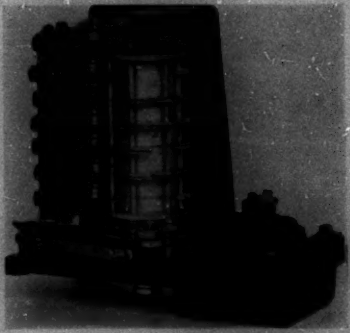

Fig. 7—Drum Unit

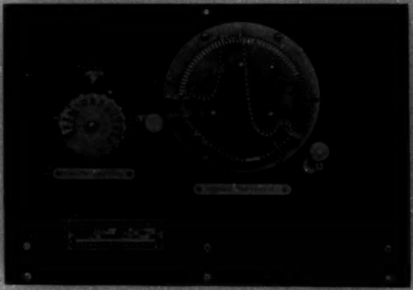

Fig. 8—Front View of Timer Panel

The operation of the drum and rotating switch and the visual picture of the color sequence as presented by the cycle percentage dial are exceedingly simple and easy to understand as opposed to the somewhat complex and inflexible fanned cam construction.

MANUAL CONTROL

Manual control of the signal lights is made possible by means of a push-button switch attached to a flexible cord. Successive, momentary depressions of the push-button switch impart electrical impulses to the drum solenoid and cause the drum to advance through the various periods in the color sequence. An important point is the fact that the traffic officer is thus forced to operate the lights in exactly the same sequence as is obtained with automatic operation. He cannot skip certain change periods as officers are sometimes prone to do with manual handles of the conventional type.

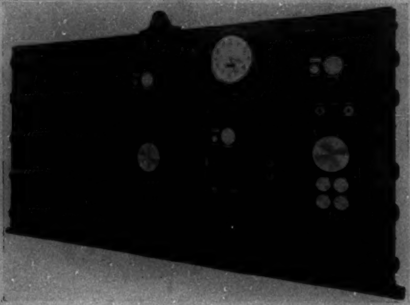

FIG. 9—TRAFFIC CONTROL SUPERVISORY BOARD IN LARGE EASTERN CITY

INHERENT DESIGN FEATURES

Auxiliary features, such as remote shut down, flashing amber and fire control, are usually obtained in interconnected systems by means of relays in each control box, one additional interconnecting cable or wire being required for each of these three features. Elimination of such relays and additional interconnecting cables is made possible by an "off, flash, fire" device in each synchronous timer. This device, while being essentially a multi-contact relay, is operated over the same wires used for remote shifting of the gears, thus resulting in a very important saving in the number of interconnecting cables required.

The timer is of universal application, that is, timers of the same identical construction can be used at isolated intersections, in non-interconnected progressive systems and interconnected progressive systems. This is of extreme importance where it is desired to operate timers in a non-interconnected progressive system initially, interconnection to be made at a later date as warranted by traffic conditions, since the necessity of replacing present timing apparatus with new and radically different construction is avoided.

The master controller, due to the fact that its supervisory feature is obtained by means of a simple pair of contacts, can, with the exception of these contacts, be of the same identical construction as an intersection timer, if so desired. Thus it can be made to serve as an intersection timer to control a set of signal lights in addition to performing its supervisory function.

INSTALLATION IN LARGE EASTERN CITY

A complete traffic signal installation, having all the flexibility described, has recently been installed in a large eastern city on one of the most congested traffic arteries in the world. The system is interconnected and automatically controlled from a supervisory board (Fig. 9). Ideal progression is given to the inbound traffic peak in the morning. Outbound traffic is similarly accommodated in the late afternoon, while average progression is maintained at other hours of the day. Program clocks automatically change the timing in accordance with the desired daily schedule for each day of the week.

CONCLUSION

It is felt that the synchronous timing device described is a real contribution in the art of efficient, flexible traffic control. Being built upon principles which are fundamentally sound and correct, it should take care of traffic requirements for years to come.

The Traffic Flow Regulator

BY C. H. BISSELL* and J. G. HUMMEL*
Member, A.I.E.E. Non-member

THE annual cost of automobile accidents in the United States is more than the annual cost of public school education, five times the country's average yearly fire loss, and more than half the amount required to maintain all the agencies of the federal government. In an attempt to promote safety, many cities have installed a large number of traffic signals at isolated corners. While the installation of these signals has perhaps promoted safety it has at the same time severely penalized traffic by needless delays and congestion during the major portion of the day, thus contributing to the two billion dollar loss previously mentioned. This discussion is confined primarily to the reduction of this loss through the installation of an efficient and properly timed control.

During certain hours of light traffic a "go" period of 15 seconds on each street may be found very satisfactory, while during rush hours, especially on Saturdays and Sundays, a "go" period of 60 seconds on each street may be demanded. With the equipment available to date, the only solution is a compromise, with the result that generally a timing of 30 seconds on each street is used. This compromise is maintained all day long, and every day of the week. During the hours when a 15-second "go" is best, the 30-second compromise "go" is 100 per cent too long, and during the times when a 60-second "go" is best, the 30-second compromise "go" is 100 per cent too short. This practise quite naturally leads to the severe criticism of causing needless delays and congestion, and the continued operation of signals in this manner may break down the obedience of motorists to traffic signals in general.

There has always been a great deal of discussion about the extreme variation in traffic. One group of adherents has contended that there was absolutely no regularity in traffic flow and has cited several freak instances of momentary variation to bear out its contention in an attempt to justify the expenditure of large amounts of money. Another group took traffic surveys and counts and found that these freak conditions occurred at not more than one intersection in twenty, or not over 5 per cent. These surveys also showed the existence of very definite peaks and valleys in the volume of traffic.

For the past six years an independent and impartial traffic survey has been carried on by the University of Wisconsin in the research of the Barney Link Fellowship and the result has just been published in its 1931 report. This report contains the result of six years of traffic research and study including the counting of millions of cars in a large number of different cities of various sizes, studied during all kinds of weather. The report shows that the occurrence of traffic peaks and valleys at 95 per cent of all intersections is so regular that definite formulas for determining the vehicular traffic have been derived for various size cities. In fact, characteristic curves for the traffic flow can be obtained by taking only five traffic counts of 12 or 18 hours each. The characteristic curve is normally typical of the traffic on all boulevards and primary streets for the city in which the data are taken.

It is a well-known fact that traffic counts and surveys have demonstrated that there are very definite traffic peaks and valleys for every week-day as well as Saturdays and Sundays. Experience has shown that these variations in traffic occur with definite regularity each day of the week. By this we mean that the light and heavy movements of traffic at each intersection occur with definite regularity at that intersection. While the traffic may differ very materially on a week-day from that on Saturday and Sunday, the average flow on every normal Monday, for instance, will be the same. Likewise the peaks and valleys of the traffic flow will occur with definite regularity on each and every day of the week, perhaps different for week-days and week-ends but with a very definite repetition. It has not been found practical or economical to send out officers to change the timing on every isolated traffic timer in the city or county to take care of each changing condition.

The only attempt to take care of this variation to date has been an attempt to control the timing simultaneously in accordance with the number of vehicles on each street. This requires some sort of electrical eye or ear or a mechanical finger in the street or highway, generally requiring the breaking up of the highway and the installation of considerable underground ducts, cables, etc., with the attendant expense of installation and equipment varying from approximately one to five thousand dollars per intersection depending upon the complexity of the installation. The result has been that few cities are able, or have felt justified, in going to this expense to take care of momentary or simultaneous variations. The most recent reaction has been that certain cities which arranged to install vehicle-actuated equipment on a rental basis feel that the expense is not justified and are looking for a more economical manner of controlling traffic efficiently.

During the past few years a group of traffic engineers has been studying this problem in an attempt to solve it in an economical manner. This study lead to the traffic flow regulator shown in Fig. 1. This device makes it possible to vary automatically the timing to

---

*Crouse-Hinds Co., Syracuse, N. Y.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

take care of these regular traffic peaks and valleys that observation or a traffic survey and count show so distinctly. Essentially this device consists of the following principal units each of which is labeled in Fig. 1:

1. An automatic timing switch.
2. One or more time allowance units.
3. An electrically-wound time switch.
4. A seven-day program unit.

The function of the automatic timing switch is the same as with any automatic traffic signal, that is, to change the signal indications at predetermined intervals and in a desired sequence.

The function of the time allowance unit is to prolong the duration of the desired or preset signal indications or to introduce indications different than those normally used.

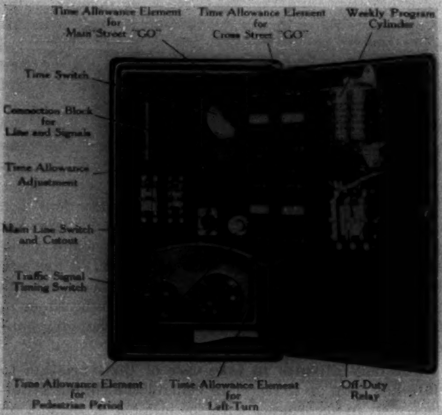

FIG. 1

The function of the time switch is to cause the desired alterations in signal indications to occur at a desired time and to continue as long as predetermined.

The function of the seven-day program unit is to permit the setting up of a program for an entire week. This program, therefore, may be different for different days of the week.

When traffic is light on both streets, the Traffic Flow Regulator operates on a short total period thus passing vehicles and pedestrians safely and rapidly. As the traffic increases, the timing is automatically extended to take care of this increase. When the rush is over, the timing is automatically shortened.

Briefly, there are fifteen different cases, or symptoms, a traffic engineer (or doctor) may be called upon to prescribe for. The nine average conditions which are encountered at practically every intersection are:

1. *The Period of Operation* by which we mean the time at which the signal is turned "on" and "off" or on a steady or flashing indication for off-duty.
2. *The Early Morning Light Traffic* which may extend up to 7:30 a. m.
3. *The Morning Rush Period* generally occurring from 7:30 to 9:00 a. m.
4. *The Morning Off-Peak Period* extending from 9:00 to 12:00 noon.
5. *The Noon-Hour Rush* generally occurring from 12:00 to 1:30 p. m.
6. *The Afternoon Off-Peak Period* occurring from 1:30 to 4:30 p. m.
7. *The Afternoon Rush* lasting from 4:30 to 6:00 p. m.
8. *The Dinner Off-Peak Period* usually evident from 6:00 to 8:00 p. m.
9. *The Evening Pleasure Driving Period* extending from 8:00 to midnight.

In the above we have simply assumed certain hours, however, it should be pointed out that there is no limitation whatsoever. Any time can be selected for the various periods; likewise, the number of periods can be varied.

In addition to the above regular conditions that are met at practically every intersection there are certain special conditions that depend more upon the location of the intersection. For instance, a timer located adjacent to a school should be capable of allotting protection to the school children while passing to and from school and to regulate the traffic expeditiously and safely at all other times. A timer located adjacent to a church should be capable of giving protection to the church-goers on Sunday and at all other times control traffic in a manner dictated by the traffic conditions.

At certain intersections a great deal of out-of-town traffic must be cared for on Saturdays, Sundays and holidays.

At an intersection where a particularly bothersome left-turn is encountered it should be possible to insert a period to take care of this left-turn whenever, and as often as desired. Likewise, the control should be capable of inserting a period for pedestrians at a corner where the pedestrian travel is severe.

At intersections where there are more than four streets or entrances, it should be possible to control the traffic in two movements during hours of light traffic and during rush hours the timer should automatically change to three or four movements or phases of control.

All of the above conditions are taken care of by the Traffic Flow Regulator. Its flexibility is almost limitless and it is possible to furnish a Traffic Flow Regulator to take care of any traffic condition.

Double Conductors for Transmission Lines

BY H. B. DWIGHT* and E. B. FARMER*
Fellow, A.I.E.E. Non-member

Synopsis.—*When two overhead conductors a few inches apart are used for each phase of a transmission line circuit, instead of one larger conductor, the reactance is reduced 20 per cent or more. Where voltage drop determines the maximum power load, as it does in many cases, reduced reactance is advantageous and increases the allowable power rating. Current-carrying capacity and corona voltage are increased. The advantages are to be balanced against the extra cost due to mechanical features, including hangers, increased cost of stringing and additional wind and ice load. Since increase in ice load is possibly the greatest disadvantage, the use of double conductors is of most interest for southern districts, where ice load is not encountered.*

BY the term double conductors employed in this paper, is meant the use of two overhead conductors instead of one, for each phase. The construction is the same as in usual transmission lines except that a second conductor is hung a few inches below the first by metallic hangers, similar to those used in electric railway catenaries. The two conductors are therefore electrically in parallel and form one effective conductor of large cross-section, without increasing the number of insulators or cross-arms.

The advantages and disadvantages of this type of construction and the classes of lines on which it might be advantageous, will be described. Formulas will be given for the calculation of the electrical characteristics, which will enable comparisons to be more easily made.

REACTANCE

An overhead double-conductor line has approximately 20 per cent less reactance than a single-conductor line of the same weight of conducting metal. In many usual cases, especially where there is not complete control of the voltage by synchronous condensers, the reactance is the most important item in determining the power rating of the line, for both the voltage drop and the stability limit of the load depend principally on the reactance. Therefore, in many instances, without increasing the weight of conductor metal, a line can be built for about one-fifth greater power rating at very little increase in cost where ice load is absent, by using double-conductor construction. This is particularly advantageous where the cost of the right-of-way is large, and it is desirable to transmit as much power per circuit as possible.

The reduction in reactance, amounting to approximately 20 per cent on practical lines, obtained by using double-conductor construction, is graphically shown in Fig. 1. The formula for the reactance of a double-conductor line, suitable for usual overhead spacings, is quite simple and is given in Appendix I, equation (1). Fig. 1 is drawn for copper conductors. It may be noted that hollow conductors and aluminum conductors of equivalent resistance have from 5 to 7 per cent less reactance than the values shown for single conductors in Fig. 1. The two small conductors of the double-conductor line may be of aluminum if desired. A formula and curve for calculating reactance of hollow conductors are given in Appendix II.

The effect of changing the distance between the two wires of the same phase, in a double-conductor line, is shown in Fig. 2. It is seen that for larger spacings than 6 inches there is little further improvement. Accordingly the discussions in this paper for the most part are based on a value of 6 inches. Curves for other conductor sizes and for other spacings between phases are very much the same as the curves of Fig. 2.

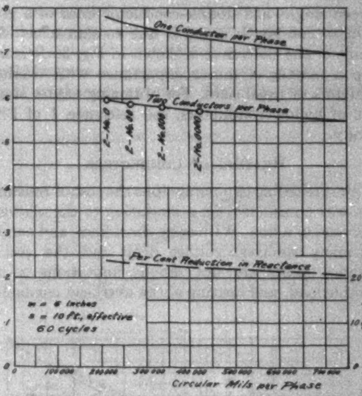

FIG. 1—COMPARISON OF REACTANCE OF SINGLE- AND DOUBLE-CONDUCTOR LINES

RESISTANCE

Another limit to the power rating of a transmission line is the cost of resistance losses. The greatest advantage of double-conductor construction in this connection is in the case of a line already built, which has higher resistance than desired and which has some mechanical margin of safety. It is possible to add a second conductor and cut the resistance in half without the necessity of taking down or scrapping the old conductor. In other words it is possible to make the reduction in resistance with only one-half as much new conductor metal as would be needed if single large-size conductors were installed. It is of course necessary that the line be strong enough to stand the extra weight including wind and ice on the second conductor. The proposition to add to the conductor metal of existing lines may be attractive at a time when the cost of conductors per pound is low.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

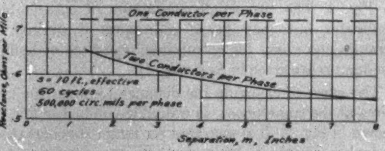

FIG. 2—CHANGE OF REACTANCE WITH SEPARATION OF PARALLELED CONDUCTORS

For new transmission lines the difference in resistance between single- and double-conductor lines of a given weight of conductor metal is due to skin effect. The amount of the difference is shown in Fig. 3. It is seen to be a matter of minor importance with overhead conductors of usual sizes. For obtaining values of skin effect of hollow conductors, see reference 1 of Bibliography.

HEATING OF CONDUCTORS

In the preceding two paragraphs the cost of resistance losses was considered, as a limitation to the allowable power load of a line. With some short lines, and notably with many tie-lines, voltage drop and the cost of resistance losses are not serious limitations to the allowable load, and heating of the overhead conductors is the practical limit encountered. In many cases, twice the normal load must be carried by one circuit as an emergency condition. It is stated in reference 4 that hard-drawn copper starts to anneal at 100 deg. cent. and that there is a reduction of 12 per cent in tensile strength due to a temperature of 130 deg. cent. for 72 hours, while a temperature of 150 deg. cent. for the same time results in a reduction of tensile strength of 30 per cent. The possibility of oxidation of joints in connectors is another reason for keeping the conductor temperature down. The current-carrying capacity of overhead conductors listed in reference 5 is based on 40 deg. cent. rise above 40 deg. cent. ambient temperature.

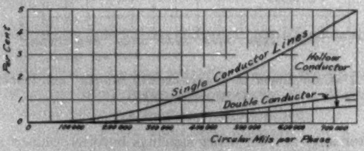

FIG. 3—INCREASE IN RESISTANCE DUE TO SKIN EFFECT AT 60 CYCLES

Tie lines have been built with very heavy overhead conductors for the purpose of avoiding overheating of the conductors. A 132-kv., 30-mile tie line from Chicago to Waukegan has been built with 750,000-cir. mil hollow copper conductors. It is stated in reference 6 that the main condition in designing the line was the heavy current to be carried.

The curves of Fig. 4 have been drawn from the table of current ratings for bare conductors, outdoor service, published in reference 3, page 466, using the ratings for 40 deg. cent. rise. It is seen that double-conductor construction increases the current-carrying capacity nearly 30 per cent, for a given weight of conductor metal. This is because the two small conductors have more surface than the single large conductor. If current ratings from the table for indoor service were used, the percentage difference between single- and double-conductor construction would be nearly the same. Hollow copper conductors, because of their large diameter, show an increased current-carrying capacity, over corresponding standard cables, though the increase is usually a small percentage. Aluminum conductors also have larger diameter and therefore greater current-carrying capacity than standard copper cables of the same resistance.

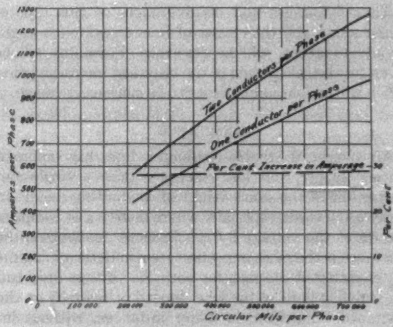

FIG. 4—CURRENT-CARRYING CAPACITY

CAPACITANCE

As is shown by Fig. 5, the capacitance of an overhead double-conductor line is 20 per cent or more greater than that of a single-conductor line of the same weight of conductor metal. This is an advantage in the case of power networks in well-settled parts of the country, where the loads and generating stations are scattered to some extent throughout the network. In such networks it is a matter of experience that synchronous condensers are used almost entirely with strong field currents, and very little with lagging power factor load and weak field currents. Consequently, an increase in line capacitance of 20 per cent means a saving of a definite amount of synchronous condensers which would otherwise need to be installed.

In other cases, where transmission lines are very long and the loads are widely separated from the generators, special attention is required to handle the line capacitance current. A sufficient number of generators must be kept always connected to the system, so that the no-load current is not an overload for them and so that the field current at rated voltage and leading power factor load does not become so small as to endanger the stability of the system. While these matters require attention, yet they seldom involve expense, particularly in the case of water-power systems where they are most likely to be noticeable, for there are practically always plenty of generators available. Accordingly even in such cases, an increase in line capacitance by using double-conductor construction, is not an economic disadvantage.

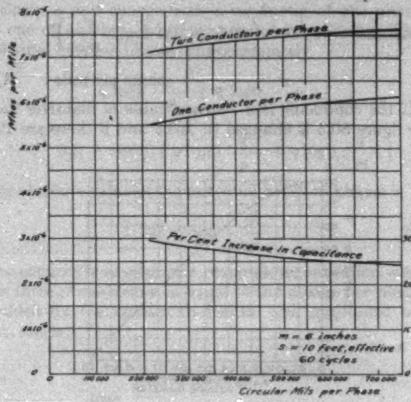

FIG. 5—COMPARISON OF CAPACITIVE SUSCEPTANCE OF SINGLE- AND DOUBLE-CONDUCTOR LINES

CORONA

Values of corona voltage, that is, the voltage at which corona starts, are shown in Fig. 6 for one and two conductors per phase, where *m*, the separation of the two conductors of the same phase, is 6 inches. Approximate formulas for calculating these results are given in Appendix IV. Very little increase in corona voltage is obtained by using two small conductors of the same type as the single large one. This is in general true at other separations than 6 inches. More increase in corona voltage is obtained by using 3 or more conductors per phase. The use of a hollow or cored conductor gives a considerable increase in corona voltage.

Measurements of the corona voltage with two and three transmission line conductors per phase are given by F. W. Peek, Jr., in "Dielectric Phenomena in High Voltage Engineering" (reference 8), page 82, and also in the first edition of the same book, pages 71 and 72, published in 1915.

If a double-conductor line and a single-conductor line have the same calculated corona voltage, the operating voltage of the double-conductor line should be kept lower than that of the other, because when corona does start, as in stormy weather, the double-conductor line has twice as many conductors on which loss takes place.

Reference should be made to the paper by P. H. Thomas, TRANS. A.I.E.E., 1909, (reference 7), in which a number of features relating to the use of two and three conductors per phase was discussed. A rather large spacing between the paralleled conductors, namely 18 inches, was assumed.

A transmission line with two conductors per phase could be constructed using a type of hanger already developed and tried out for electric railway catenaries. It would be more expensive than a single-conductor line of equal mechanical strength. The duty on the towers, and their height, would be greater due to approximately twice as much wind and ice load. More clearance would be required and shorter spans might be needed. More margin of safety would be required in the tensile strength of the conductors, for although each might be pulled up to the proper tension, it would not be certain that one conductor would not take more than its share of the tensile load at some later time. The cost of stringing the conductors would be greater. Since the increase in ice load is perhaps the greatest disadvantage, the use of double conductors is of most interest for southern districts, where ice load is not encountered.

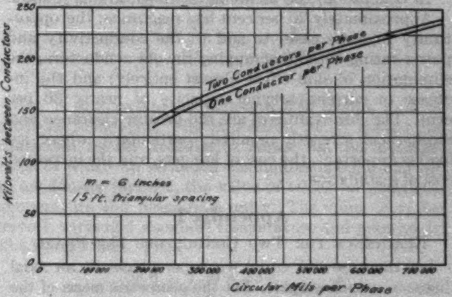

FIG. 6—CORONA VOLTAGE AT SEA LEVEL

The additional cost due to the mechanical features of the double-conductor construction is to be balanced against the value of the advantages to be obtained. If circumstances are such that the voltage drop in the line must not be more than a certain percentage, then 20 per cent reduction in reactance permits a corresponding increase in the allowable power load. The additional cost, is, in such a case, to be compared with 20 or 25 per cent of the entire cost of the transmission line. Such a case assumes that methods of controlling the voltage as by synchronous condensers are not considered applicable, and that the only way in which the power can be increased is by decreasing the reactance or providing additional circuits.

An increase in current-carrying capacity or in corona voltage might be an additional advantage, but such an increase would probably not by itself justify the special construction, for ratings now in use. The current-carrying capacity or corona voltage of a single-conductor line could usually be increased 30 per cent without increasing the cost of the entire transmission line more than a few per cent, by using a heavier conductor or one of about 30 per cent larger diameter. The cost of the conductors is only a fraction of the cost of the entire line. Such a conductor, however, will not give 20 per cent less reactance. The large reduction in reactance is therefore the most important feature of the double-conductor construction.

In conclusion, the advantages shown are as follows: Approximately 20 per cent less reactance; the opportunity in some cases to add to the conductivity and power rating without scrapping the old conductors; the elimination of skin effect almost entirely; and the increase in current-carrying capacity of nearly 30 per cent. The disadvantages are the greater clearance and mechanical strength required, particularly where ice load is important, the cost of hangers, and the increased cost of installation.

Appendix I

REACTANCE FOR TWO CONDUCTORS PER PHASE

Let there be two equal wires per phase, at an axial distance m inches apart. Let the geometric mean of the spacings between the phases be s inches. Then the reactance will be approximately the same as for equilateral spacing of s inches. If s is considerably larger than m, the current will divide practically equally between the two wires of each phase.

Reactive drop in one wire is approximately, for a three-phase system,

$$= j2\pi f\,10^{-9}\left[\frac{I}{2}\left(\frac{1}{2}+2\,\text{logn}\,\frac{p}{\rho}\right)+\frac{I}{2}\,2\,\text{logn}\,\frac{p}{m}\right.$$

$$\left.+I(-0.5+j0.866)\,2\,\text{logn}\,\frac{p}{s}+I(-0.5-j0.866)\,2\,\text{logn}\,\frac{p}{s}\right]$$

volts per cm.

where ρ is the radius of the wires, and p is a certain large distance up to which flux is counted. As p cancels out, the result is the same no matter how large p may be. The term logn denotes natural logarithm. Reactive drop

$$= j\,\frac{2\pi f\,10^{-9}}{2}\,I\left(\frac{1}{2}+2\,\text{logn}\,\frac{s}{\rho}+2\,\text{logn}\,\frac{s}{m}\right)$$

$$= j\pi f I\,10^{-9}\left(\frac{1}{2}+2\,\text{logn}\,\frac{s^2}{m\,\rho}\right)\text{ volts per cm.}$$

Changing units,

$$\text{Reactance} = \pi f\,10^{-6}\left(80.5+741\,\log_{10}\frac{s^2}{m\rho}\right)$$

$$\text{ohms per mile} \qquad (1)$$

If the conductor is a 7-strand cable of diameter 2ρ, the figure 80.5 is changed to 103.3 and if there are 19 strands, the figure becomes 89.3. (See reference 9, page 127, for other numbers of strands.)

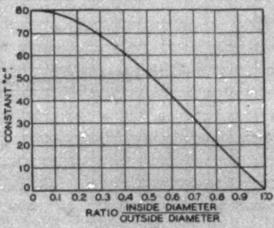

FIG. 7—CONSTANT c FOR USE IN EQUATION (2), REACTANCE OF TUBULAR CONDUCTOR

Appendix II

REACTANCE OF TUBULAR OR HOLLOW CONDUCTOR

The reactance of a tubular conductor is

$$2\pi f\,10^{-6}\left(c+741\,\log_{10}\frac{s}{\rho}\right)\text{ ohms per mile} \qquad (2)$$

where s is the geometric mean of the axial spacings between phases, 2ρ is the diameter of the conductor and c is read from Fig. 7. The formula used in drawing the curve for c is given in reference 9, page 137, equation (5), or in other books.

Formula (2) is in most practical cases a close approximation for the reactance of a hollow stranded conductor. It may be noted that the reactance of a standard conductor having 37 strands, and 18 strands in the outer layer, is given very closely by the formula for a solid wire.

Appendix III

CAPACITANCE FOR TWO CONDUCTORS PER PHASE

Let there be a three-phase system with two equal conductors per phase of radius ρ and at an axial distance m. Let the geometric mean of the spacings between the phases be s. Then the capacitance will be approximately the same as for equilateral spacing s. If s is considerably larger than m, the charge will divide almost equally between the two conductors of each phase. Let the charge on each of the conductors of the first phase be $q/2$ per cm. For the fundamentals of this type of calculation see reference 9, pages 142, 143 and 152, or other books.

Carry a unit charge from a conductor of one phase to one of another, assuming equilateral spacing. The potential between phases is approximately

$$q \operatorname{logn} \frac{s}{\rho} + q \operatorname{logn} \frac{s}{m}$$

$$-(-0.5 + j.866)\left(q \operatorname{logn} \frac{s}{\rho} + q \operatorname{logn} \frac{s}{m}\right)$$

The absolute value of the potential between phases is

$$1.732\, q \operatorname{logn} \frac{s^2}{m\rho} \qquad (3)$$

The capacitive susceptance required in connection with the three-phase circuit is equal to the charge per phase divided by the voltage to neutral and multiplied by $2\pi f$, and is

$$\frac{2\pi f}{\operatorname{logn} \dfrac{s^2}{m\rho}} \text{ in absolute units.}$$

$$\text{Changing units,} \quad b = \frac{2\pi f \times 38.8 \times 10^{-9}}{\log_{10} \dfrac{s}{\sqrt{(m\rho)}}} \qquad (4)$$

$$= \frac{4\pi f\, 38.8 \times 10^{-9}}{\log_{10} \dfrac{s^2}{m\rho}} \text{ mhos per mile} \qquad (5)$$

The capacitance of a double-conductor line, to the first approximation, is therefore the same as that of a single-conductor line the radius of whose conductors is $\sqrt{(m\rho)}$.

Appendix IV

CORONA VOLTAGE

By corona voltage is meant the voltage at which corona starts to form on transmission line conductors in fair weather. This is an advisable limit of operating voltage. It depends on the potential gradient in volts per cm. at the surface of the conductors.

If in a double-conductor transmission line s/m is comparatively large, the charge may be taken to be equally divided between the two conductors per phase. If $q/2$ is the charge per cm. of conductor, the gradient in absolute units at the surface of one of the wires is $\dfrac{q}{\rho}$ due to the charge on that wire. This component of the gradient is, for equilateral triangular spacing between phases,

$$\frac{q}{\rho} = \frac{e_o}{2\rho \operatorname{logn} \dfrac{s}{\sqrt{(m\rho)}}} \text{ in absolute units,}$$

$$\text{since} \qquad e_o = 2q \operatorname{logn} \frac{s}{\sqrt{(m\rho)}} \text{ to neutral,}$$

from equation (3), Appendix III.

In order to include the component of gradient due to the other conductor of the same phase, the above value of gradient should be multiplied by $1 + \dfrac{2\rho}{m}$ according to equation (**15**) and Table II of the paper *Three-Phase Multiple-Conductor Circuits*, by Edith Clarke, see page 809 of this issue. This factor was given for use when the value of $\dfrac{m}{2\rho}$ is as low as 5.

Then if g_o is the gradient at which corona forms,

$$e_o = \frac{2\, g_o\, \rho}{1 + \dfrac{2\rho}{m}} \operatorname{logn} \frac{s}{\sqrt{(m\rho)}}$$

If g_o is in kilovolts per inch and ρ in inches, e_o is in kilovolts to neutral. The expression for e_o should be multiplied by an irregularity factor m_o, an average value of which for stranded conductors is 0.85, and by an air density factor δ, the value of which for standard temperature and pressure is unity. The value of g_o for smooth wires and standard temperature and pressure is 53.6 kv. per inch. Then

$$e_o = \frac{53.6 \times 2.30\, m_o \delta \rho}{1 + \dfrac{2\rho}{m}} \log_{10} \frac{s^2}{m\rho} \qquad (6)$$

For stranded conductors at normal temperature and pressure,

$$e_o = \frac{105\, \rho}{1 + \dfrac{2\rho}{m}} \log_{10} \frac{s^2}{m\rho} \text{ kilovolts to neutral,} \qquad (7)$$

for double-conductor lines, dimensions being in inches.

By equation (35′), page 302, reference 8,

$$e_o = 105\, \rho \log_{10} \frac{s}{\rho} \qquad (8)$$

for single-conductor lines, with $m_o = 0.85$. For a description of calculations of corona, see reference 8, Chapter X.

Three-Phase Multiple-Conductor Circuits

BY EDITH CLARKE*

Associate, A.I.E.E.

Synopsis.*—During the past year the subject of power transmission by multiple-conductor circuits has received considerable attention. The formulas and estimating curves given in the paper may therefore be of interest at this time.*

Formulas are developed for the inductance and capacitance to neutral per phase and the approximate corona starting voltage of perfectly transposed, multiple-conductor, three-phase transmission lines having any number of conductors per phase.

For certain special arrangements of the conductors, curves are given for the 60-cycle reactance, capacity susceptance, and corona starting voltage. These curves show the effect of variations, throughout their practical range, in conductor diameter, spacing between phases and between conductors of the same phase. Two, three, four and five conductors per phase are considered.

A comparison is made of multiple- and single-conductor circuits with respect to charging current, voltage at no load, power which can be carried with the same voltage drop, and stability.

INTRODUCTION

MULTIPLE or split conductors were proposed in 1909 by P. H. Thomas in a paper[1] before the Institute. In this paper Mr. Thomas pointed out the advantage of split conductors in increasing the power which may be transmitted at a given voltage drop. Since then, at irregular intervals, the use of two or more conductors per phase has been suggested by transmission engineers for various contemplated projects. At such times it was found advantageous to have available for estimating purposes, curves giving the 60-cycle reactance, the capacity susceptance and the disruptive critical voltage for various proposed arrangements of the multiple-conductor circuits. These curves were made up from time to time as new arrangements of the conductors were considered.

The recent revival of interest in the subject has suggested that these curves be assembled and brought to the attention of those who may find use for them in estimating the performance of multiple-conductor circuits. The curves include various arrangements of two, three, four, and five conductors per phase.

I—Electrical Characteristics of Multiple-Conductor Circuits

TRANSPOSED LINES

When the conductors of a three-phase transmission line are unsymmetrically arranged, unless the conductors are transposed, the inductance and capacitance to neutral of the three phases will be unequal and the currents under normal operating conditions unbalanced. When a multiple-conductor line is so transposed that each conductor occupies each of the tower positions or its equivalent for equal distances, the phases being rotated in cyclic order, the total inductance and capacitance to neutral of the three phases will be equal. Also, the total inductance and capacitance of each conductor will be the same. Therefore, with balanced voltages applied, the phase currents will be balanced and each will divide equally among the conductors of that phase. When the line is not transposed, or only partly transposed, an exact solution may be obtained by the use of symmetrical components. In the general case, with balanced voltages applied, there will be negative and zero sequence currents as well as positive sequence currents. Approximate results may be obtained by considering only the positive sequence currents and by using for inductance and capacitance to neutral the average of the three positive sequence inductances and capacitances, respectively. This is equivalent to using the values of inductance and capacitance which the line would have if it were perfectly transposed.

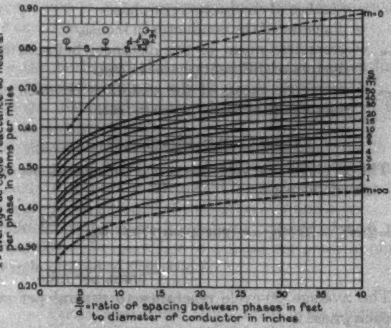

FIG. 1—TWO CONDUCTORS PER PHASE ARRANGED VERTICALLY

S = horizontal distance between adjacent phases in feet
m = distance between conductors of the same phase in feet
d = diameter of the conductor in inches

In the work which follows a completely transposed line will be assumed.

INDUCTANCE

A formula for the average inductance to neutral per mile of each conductor of a perfectly transposed three-phase transmission line having n conductors per phase

---

*Central Station Engg. Dept., General Electric Co., Schenectady, N. Y.

1. For references see Bibliography.

Presented at the Northeastern District Meeting of the A.I.E.E., Providence, R. I., May 4-7, 1932.

is derived in Appendix A. The inductance will vary along the line with the transpositions, but the average inductance per mile of all conductors to neutral will be the same. Since the n conductors of the phase are in parallel, the average inductance per phase will be the *nth* part of the inductance per conductor.

It has been found convenient in using curves for estimating purposes to express the diameter of the conductors in inches while the spacings between phases and between conductors of the same phase are in feet.

From (**9a**), Appendix A, the average inductance to neutral per mile of each conductor is

$$L_c = 0.08047 + 0.74113 \log_{10} \frac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}$$

millihenrys per mile (**1**)

The average inductance per phase, L, will be the *nth* part of the inductance per conductor, therefore

$$L = \frac{1}{n}\left[0.08047 + 0.74113 \log_{10} \frac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}\right]$$

millihenrys per mile (**2**)

where

n = number of conductors per phase.

d = diameter of the conductor in inches.

S_{gm} = geometric mean of the distances between conductors of different phases in feet.

m_{gm} = geometric mean of the distances between conductors of the same phase in feet.

60-CYCLE REACTANCE

The average 60-cycle reactance to neutral per mile of each conductor is

$$x_c = 2\pi f L_c = 377\,L_c = 0.03034 + 0.27941 \log_{10} \frac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}$$

ohms per mile (**3**)

The average 60-cycle reactance to neutral per mile of each phase is

$$x = 377\,L = \frac{x_c}{n}$$

$$= \frac{1}{n}\left[0.03034 + 0.27941 \log_{10} \frac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}\right]$$

ohms per mile (**4**)

SOLID, STRANDED AND HOLLOW CONDUCTORS

The internal inductance[2] of a stranded conductor is greater than that of a solid conductor of the same outside diameter, while that of a hollow conductor is less. The internal 60-cycle reactance of a solid conductor in ohms per mile is given by the first term on the right hand side of (**3**), while the external reactance is given by the second term.

Table I gives a plus or minus correction, ϵ, to be added to the 60-cycle phase reactance calculated by (**4**) to obtain the correct reactance per phase for stranded and hollow multiple conductors. These corrections were calculated by using for stranded conductors the formulas given in "Transmission Line Formulas," by H. B. Dwight, page 127, and for hollow conductor, equation (**14**) p. 827, Pender's "Handbook for Electrical Engineers."

For hollow or stranded multiple conductors

$$x = \epsilon + \frac{1}{n}\left[0.03034 + 0.27941 \log \frac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}\right]$$

ohms per mile (**5**)

CAPACITANCE

Dr. Kennelly in his discussion[3] of Mr. Thomas' paper,[1] by applying the theorem of the propagation of electric disturbances in free space at the speed of light to multiple conductor circuits, points out that the capacitance to neutral in statfarads per cm. is the reciprocal of the external inductance to neutral in abhenrys per cm. The first term on the right hand side of (**8a**), Appendix A, is the external and the second the internal inductance. Therefore, for a perfectly transposed multiple-conductor circuit the average capacitance to neutral per cm. for each conductor will be

$$C_c = \frac{1}{2 \quad \log_e \dfrac{2\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}} \text{ statfarads per cm.} \quad (\mathbf{6})$$

where d, S_{gm} and m_{gm} are expressed in the same units.

Expressing (**6**) in practical units with S_{gm} and m_{gm} in feet and d in inches, the average capacitance to neutral per mile for each conductor is

$$C_c = \frac{0.03883}{\log_{10} \dfrac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}} \text{ microfarads per mile} \quad (\mathbf{7})$$

TABLE I—ϵ—CORRECTION FOR STRANDED AND HOLLOW CONDUCTORS

Conductors per phase	Stranded conductors				Hollow conductors					
	No. of strands				Ratio of internal to external diameter					
	7	19	37	61	0	0.20	0.4	0.6	0.8	1.0
1	0.0086	0.0033	0.0017	0.0010	0	−0.0022	−0.0075	−0.0145	−0.0222	−0.0303
2	0.0043	0.0017	0.0009	0.0005	0	−0.0011	−0.0038	−0.0073	−0.0111	−0.0152
3	0.0029	0.0011	0.0006	0.0004	0	−0.0007	−0.0025	−0.0048	−0.0074	−0.0101
4	0.0021	0.0008	0.0004	0.0003	0	−0.0005	−0.0019	−0.0036	−0.0056	−0.0076
5	0.0017	0.0007	0.0003	0.0002	0	−0.0004	−0.0015	−0.0029	−0.0044	−0.0061

The average capacitance to neutral per mile, C, for each phase will be n times the capacitance per conductor, therefore

$$C = \frac{0.03883\, n}{\log_{10} \dfrac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}} \text{ microfarads per mile} \qquad (8)$$

60-Cycle Capacity Susceptance

The average capacity susceptance to neutral per mile of each conductor for a frequency of 60 cycles will be

$$b_c = 2\pi f C_c = 377 C_c = \frac{14.64}{\log_{10} \dfrac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}} \text{ micromhos per mile} \qquad (9)$$

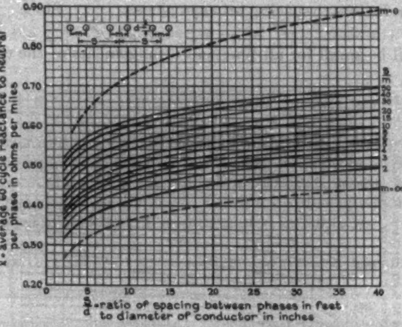

FIG. 2—TWO CONDUCTORS PER PHASE ARRANGED HORIZONTALLY

60-cycle reactance as affected by S/d and S/m

S = distance between centers of adjacent phases in feet

m = distance between conductors of the same phase in feet

d = diameter of the conductor in inches

The average 60-cycle capacity susceptance to neutral per mile of each phase, will be

$$b = 377C = nb_c = \frac{14.64\, n}{\log_{10} \dfrac{24\,(S_{gm})^n}{d\,(m_{gm})^{n-1}}} \text{ micromhos per mile} \qquad (10)$$

Relation Between 60-Cycle Reactance and Capacity Susceptance

If the product of capacitance and external inductance is unity in absolute units, it follows that there is a definite relation between 60-cycle reactance and capacity susceptance.

Transposing (5) and multiplying by (10) there results

$$b\left[x - \frac{0.0303}{n} - \epsilon\right] = 4.09 \qquad (11)$$

When x, the 60-cycle reactance to neutral per phase in ohms is known, b, the capacity susceptance per phase in micromhos may be calculated from the following formula:

$$b = \frac{4.09}{x - \left(\dfrac{0.0303}{n} + \epsilon\right)} \text{ micromhos per mile} \qquad (12)$$

Should b be known, x may be obtained, thus,

$$x = \frac{4.09}{b} + \frac{0.0303}{n} + \epsilon \text{ ohms per mile} \qquad (13)$$

60-Cycle Reactance and Capacity Susceptance Curves for Multiple-Conductor Circuits

Equations (4) and (10) give the average 60-cycle reactance and capacity susceptance to neutral per mile for each phase of a perfectly transposed multiple conductor circuit, having any number of conductors per phase and any arrangement of the conductors.

For certain symmetrical arrangements of phases and conductors in the phases, the reactance and capacity susceptance may be expressed in terms of the ratios S/d and S/m, where

S = the horizontal distance between the center lines of adjacent phases in feet.

m = the distance between adjacent conductors of the same phase in feet.

d = the diameter of the conductor in inches.

In Appendix B, formulas for 60-cycle reactance and capacity susceptance for special multiple-conductor circuits are given in terms of the ratios S/d and S/m.

The following cases have been considered and the average 60-cycle reactance to neutral per phase in ohms per mile plotted in Figs. 1 to 7:

1. Two conductors per phase
    a. Vertical arrangement of conductors in the same phase.
    b. Horizontal arrangement of conductors in the same phase.
2. Three conductors per phase
    a. Vertical arrangement of conductors in the same phase.
    b. Conductors of the same phase at the corners of an equilateral triangle.
3. Four conductors per phase
    a. Vertical arrangement of conductors in the same phase.
    b. Conductors of the same phase at the corners of a square.
4. Five conductors per phase
    a. Vertical arrangement of conductors in the same phase.

These curves are applicable for all practical conductor diameters, spacings between phases and between conductors of the same phase. Since they are for solid conductors, the correction, ϵ, Table I, should be applied when necessary.

Fig. 8 gives the average 60-cycle capacity susceptance to neutral per phase in micromhos per mile for two conductors per phase, arranged vertically, case *Ia*. Fig. 1 gives the corresponding 60-cycle reactance.

Since 60-cycle capacity susceptance is readily calculated from equation (**12**) when the reactance is known, curves for the capacity susceptance of the other conductor arrangements are not given.

CORONA

In a perfectly transposed multiple-conductor circuit, since each conductor occupies each of the tower positions for equal distances, the corona-starting voltage for all conductors will be approximately the same. As a conductor is changed from one tower position to another, in general, it will have a different corona-starting voltage in each position.

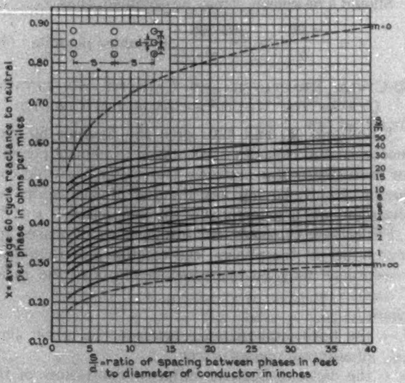

FIG. 3—THREE CONDUCTORS PER PHASE ARRANGED VERTICALLY

60-cycle reactance as affected by S/d and S/m
S = horizontal distance between adjacent phases in feet
m = distance between adjacent conductors of the same phase in feet
d = diameter of the conductor in inches

In Appendix C, by Mr. S. B. Crary, a formula is developed for the disruptive critical voltage, or the corona-starting voltage, for any conductor of a multiple-conductor circuit. If the conductor which has the lowest disruptive critical voltage is designated *II-1*, as in Fig. 10, the lowest disruptive critical voltage of the system will be given by (**8c**), if 1 and *1* are interchanged.

Introducing the irregularity and air density factors,[4] M_0 and δ, respectively, and multiplying numerator and denominator of the fraction in (**8c**) by d, e_0, the lowest corona starting voltage of the system will be given by (**14**).

$$e_0 = \frac{61.5\,M_0\delta d\log_{10}\dfrac{2\sqrt{(S_{11}.S_{12}\ldots S_{1n})(S_{11}.S_{12}\ldots S_{1n})}}{dm_{12}\ldots m_{1n}}}{1+\sqrt{\left[\sum\dfrac{d}{m_{1n}}\cos\theta_{1n}\right]^2+\left[\sum\dfrac{d}{m_{1n}}\sin\theta_{1n}\right]^2}}$$

kv. to neutral (**14**)

where

e_0 = line-to-neutral corona starting voltage in kv.
M_0 = irregularity factor = 0.98 − 0.93 for roughened or weathered wires. = 0.87 − 0.83 for seven-strand cables.
δ = air density factor = $3.92b/(273+t)$ = 1.00 at 76 cm. barometer and 25 deg. cent.
where b = barometric pressure in cm. and t = temperature in deg. cent.

d, m, and S are in inches.

The formulas for disruptive critical voltage, given by (**8c**) and (**14**), are based on the assumptions that the charges on the three phases are balanced, and the charge per unit length is the same for all conductors of the same phase. The field distortion in the vicinity of a conductor due to charges on conductors of the other two phases will depend upon the ratio of diameter of conductors to spacing between phases, $\frac{d}{S}$. Since $\frac{d}{S}$ will be small for all practical arrangements of the conductors in a multiple conductor circuit, the field distortion due to the charges on the other two phases will have a negligible effect on the corona starting voltage. The field distortion due to the charges on conductors of the same phase will depend upon $\frac{d}{m}$, the ratio of diameter of conductors to spacing between conductors of the same phase, and may have an appreciable effect upon the corona starting voltage. This is evident from

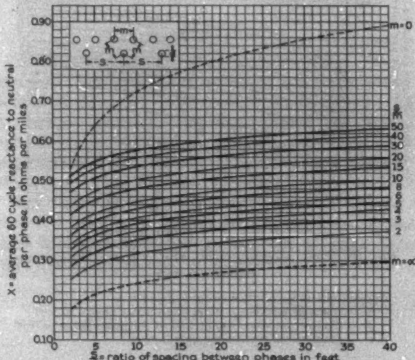

FIG. 4—THREE CONDUCTORS PER PHASE ARRANGED AT THE CORNERS OF AN EQUILATERAL TRIANGLE

60-cycle reactance as affected by S/d and S/m
S = distance between centers of adjacent phases in feet
m = side of triangle in feet
d = diameter of conductors in inches

inspection of the denominator of the fraction in (**14**). As the ratio of diameter to spacing between conductors decreases, the field distortion will decrease and finally become negligible for very small values of $\frac{d}{m}$. When $\frac{d}{m}$ is small relative to unity, the denominator of the fraction in (**14**) approaches unity; the numerator of the fraction will then give the corona starting voltage.

As a first approximation, the corona starting voltage may be calculated from the numerator of the fraction in (**14**). When greater accuracy than this is required, the approximate corona-starting voltage may be corrected by dividing it by D, the denominator of the fraction in (**14**).

Let

$$D = 1 + \sqrt{\left[\sum \frac{d}{m_{1n}} \cos \theta_{1n}\right]^2 + \left[\sum \frac{d}{m_{1n}} \sin \theta_{1n}\right]^2}$$

$$= 1 + k\frac{d}{m} \qquad \mathbf{(15)}$$

where d and m are in the same units and k depends upon the arrangement and the number of conductors in the phase. Values of k corresponding to seven special arrangements of conductors in multiple conductor circuits were calculated by (**15**) and tabulated in Table II.

TABLE II—VALUES OF k AND x_k TO BE USED IN CONNECTION WITH FIG. 9 TO OBTAIN CORONA STARTING VOLTAGE

Conductors per phase	Arrangement of conductors in the phases	k To be substituted in equation (15) to obtain D	x_k To be substituted in equation (18) to obtain x_m
2	vertical	1.0	0.056
2	horizontal	1.0	0.056
3	vertical	1.5	0.112
3	at corners of an equilateral triangle	1.732	0.084
4	vertical	1.833	0.179
4	at corners of a square	2.121	0.112
5	vertical	2.083	0.251

If the numerator of the fraction in (14) is compared with the formula for minimum 60-cycle reactance given in (**11a**), Appendix A, it will be noticed that the argument of the logarithm is the same in both equations. For convenience, corona-starting voltage will be expressed in terms of x_m, the minimum 60-cycle reactance of any conductor.

Replacing the logarithm in (14) by its value from (**11a**), and replacing the denominator by D,

$$e_0 = \frac{61.5\, M_0 \delta d \, \dfrac{x_m - 0.03034}{0.27941}}{D} \qquad \mathbf{(16)}$$

Substituting 0.87 for M_0 and 1.0 for δ in (**16**) and multiplying both sides of the equation by $\sqrt{3}$, the line-to-line corona-starting voltage, E_0, is obtained.

$$E_0 = \frac{332\, d\, (x_m - 0.03034)}{D} \text{ kv. line-to-line} \qquad \mathbf{(17)}$$

In Appendix B, formulas are given for x, the average 60-cycle reactance per phase for special arrangements of the multiple conductor circuits. These are plotted in Figs. 1 to 7. In Appendix A it is shown that x_m the minimum 60-cycle reactance for a conductor in ohms per mile may be obtained from x_c its average 60-cycle reactance by subtracting a value, x_k, which is approximately constant for any given number of conductors per phase and arrangement of conductors in the phase. Values of x_k for special conductor arrangements are derived from (**13a**), Appendix A and tabulated in Table II. x_m may be calculated from Figs. 1 to 7 and Table II, by means of (**18**).

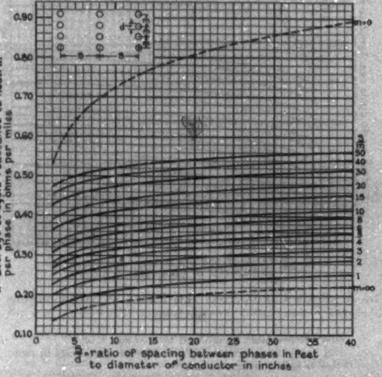

FIG. 5—FOUR CONDUCTORS PER PHASE ARRANGED VERTICALLY

60-cycle reactance as affected by S/d and S/m

S = horizontal distance between adjacent phases in feet

m = distance between adjacent conductors of the same phase in feet

d = diameter of the conductor in inches

$$x_m = x_c - x_k = nx - x_k \qquad \mathbf{(18)}$$

Fig. 9, plotted from (**17**) when $D = 1$, gives a first approximation of the line-to-line corona-starting voltage in kv., expressed in terms of minimum 60-cycle reactance to neutral of any conductor in ohms per mile, and the diameter of the conductor in inches. It is applicable to both multiple- and single-conductor circuits. The reactance to be used is that for solid conductors of the given diameter and spacings.

From Fig. 9 and Figs. 1 to 7 the approximate diameter which is required to avoid corona at specified spacings and voltage for any of the special conductor arrangements considered, may be determined by the following procedure:

a. Assume *d*, the diameter of the conductor.

b. From Figs. 1 to 7 read x, the average 60-cycle reactance per phase corresponding to the specified number of conductors per phase, arrangement of conductors, and calculated values of S/d and S/m.

c. Multiply x, the reactance per phase, by n, the number of conductors per phase, to obtain x_c, the average reactance per conductor.

d. From x_c, the average reactance per conductor, calculate x_m, the minimum reactance, by subtracting the appropriate value of x_k given in Table II. (See equation (18).)

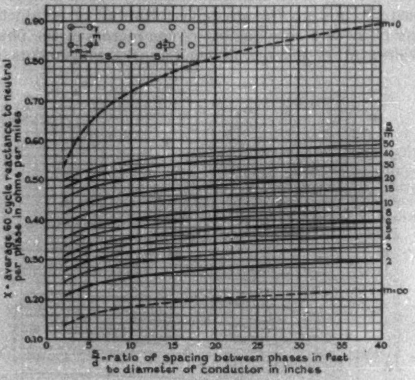

FIG. 6—FOUR CONDUCTORS PER PHASE AT THE CORNERS OF A SQUARE

60-cycle reactance as affected by S/d and S/m
S = distance between centers of adjacent phases in feet
m = side of square in feet
d = diameter of the conductor in inches

e. From Fig. 9 read E_0', a first approximation of the line-to-line corona-starting voltage corresponding to the assumed diameter, *d*, and the minimum reactance, x_m. This will be very nearly the correct value of the corona-starting voltage when the ratio of d/m is small relative to unity.

f. Calculate d/m and read k from Table II corresponding to the given number and arrangement of conductors. Substitute d/m and k in (15) to obtain D, d and m being in the same units.

g. Divide the value of E_0' read from Fig. 9 by D to obtain the corrected corona-starting voltage, E_0.

h. If E_0 obtained from (*g*) is greater than the operating voltage, corona will be avoided. If E_0 is less than the operating voltage, a larger diameter should be selected and the process repeated.

II—Comparison of Multiple- and Single-Conductor Circuits

REACTANCE AND CAPACITY SUSCEPTANCE

The upper dotted curve in Figs. 1 to 7 for $m = o$ gives the average 60-cycle reactance to neutral of the three phases of a single-conductor circuit with flat arrangement of conductors. It also gives the average reactance per mile of each phase of the perfectly transposed line. The reactance is plotted in terms of S/d, the ratio of the distance between adjacent conductors in feet to the diameter of the conductor in inches. The curve, which is the same on all seven figures, has been repeated for convenience in comparing the reactance of the single-conductor circuit with that of multiple-conductor circuits. Since the curve is for solid conductors, the correction from Table I corresponding to $n = 1$ should be applied for stranded or hollow conductors.

As m increases from 0 to ∞, the reactance per phase of the multiple conductor decreases. The lower dotted curves for $m = \infty$ apply when the conductors of the phase are so far apart that all mutual effects disappear and there are n separate parallel circuits.

From Figs. 1 to 7 it may be seen that the reactance per phase of a multiple-conductor circuit is always less than that of the single-conductor circuit, the diameter and spacing between adjacent phases being the same. The reactance of one conductor of the multiple-conductor circuit, however, is greater than that of a conductor of the single-conductor circuit.

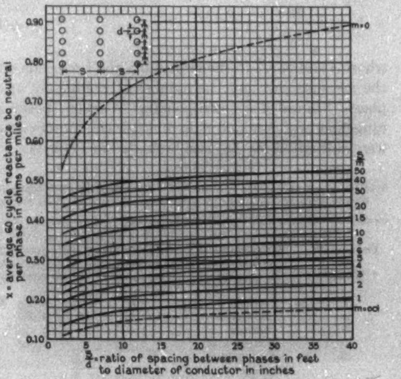

FIG. 7—FIVE CONDUCTORS PER PHASE ARRANGED VERTICALLY

60-cycle reactance as affected by S/d and S/m
S = horizontal distance between adjacent phases in feet
m = distance between adjacent conductors of the same phase in feet
d = diameter of the conductor in inches

In Fig. 8 the lower dotted curve gives the 60-cycle capacity susceptance to neutral of the single-conductor circuit. The upper dotted curve gives the upper limit of the capacity susceptance per phase as the spacing between the conductor of the phase is indefinitely increased. It is evident that the capacity susceptance per phase for the multiple-conductor circuit is greater than that of the single-conductor circuit for the same S/d, while the capacity susceptance per conductor is less.

DIAMETER TO AVOID CORONA

Fig. 9 gives the approximate diameter required to avoid corona at a given voltage in terms of x_m, the minimum 60-cycle reactance of any conductor. Since the reactance per conductor is greater in the multiple- than in the single-conductor circuit, from Fig. 9 it follows that a smaller diameter is required to avoid corona in the multiple- than in the single-conductor circuit. With the same conductor diameter, the multiple-conductor circuits can be operated at a higher voltage without corona than the single-conductor circuit.

CHARGING CURRENT AND RISE IN VOLTAGE AT NO-LOAD

At a given voltage and frequency the charging currents on the multiple- and single-conductor circuits are directly proportional to their respective capacitances to neutral per phase. Since the larger current flows through the smaller inductance and vice versa, the rise in voltage at no-load is practically the same for both the multiple- and single-conductor circuits. These statements follow from the transmission line equations[5] (**19**) and (**20**) under no-load conditions, *i.e.* $I_r = 0$.

$$e_s = e_r \cosh\sqrt{ZY} + I_r Z\left(\frac{\sinh\sqrt{ZY}}{\sqrt{ZY}}\right) \qquad \mathbf{(19)}$$

$$I_s = I_r \cosh\sqrt{ZY} + e_r Y\left(\frac{\sinh\sqrt{ZY}}{\sqrt{ZY}}\right) \qquad \mathbf{(20)}$$

where

e_s and e_r = voltage to neutral at sending and receiving end of line respectively in volts.

I_s and I_r = the corresponding phase current in amperes.

$Z = l\,(r + jx) = l\,(r + j\,2\pi fL)$ = total impedance of one phase to neutral in ohms.

$Y = l\,(g + jb) = l\,(o + j\,2\pi fC)$ = total admittance of one phase to neutral in mhos.

r, L, g and C = resistance, inductance, leakance and capacitance respectively to neutral per mile.

l = length of line in miles.

Replacing the hyperbolic terms in (**19**) and (**20**) by their equivalent series, and setting $I_r = 0$, at no load

$$e_g = e_r\left(1 + \frac{ZY}{2} + \frac{Z^2Y^2}{24} + \ldots\ldots\right) \qquad \mathbf{(21)}$$

$$I_g = e_r Y\left(1 + \frac{ZY}{6} + \frac{Z^2Y^2}{120} + \ldots\ldots\right) \qquad \mathbf{(22)}$$

For single-conductor circuits the product of inductance and capacitance varies but slightly throughout the practical range of conductor diameters and spacings. Therefore, for a given frequency and length of line, the terms in parenthesis in (**21**) and (**22**) are substantially constant. The effect of resistance, and variations in the product of inductance and capacitance, on the hyperbolic terms used in transmission line calculation are shown graphically in "Simplified Transmission Line Calculations" by the author, *General Electric Review*, May 1926. In all practical cases these effects are small.

In multiple-conductor circuits the inductance per phase is decreased and the capacitance increased over that of the single-conductor circuit in approximately the same ratio, therefore the product of inductance and capacitance will not be greatly changed. This product, in general, will be slightly less for multiple- than for single-conductor circuits, but it will not be more than 5 per cent less. The effect of this variation on the terms in parenthesis will be insignificant except for very long lines. It is therefore evident from (**22**) that the charging current varies directly with the capacitance, and from (**21**) that the rise in voltage at no-load for the single- and multiple-conductor circuits is substantially the same.

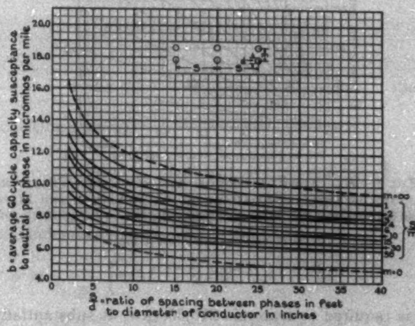

FIG. 8—TWO CONDUCTORS PER PHASE ARRANGED VERTICALLY

60-cycle capacity susceptance as affected by S/d and S/m

S = horizontal distance between adjacent phases in feet

m = distance between conductors of the same phase in feet

d = diameter of the conductor in inches

POWER TRANSMITTED UNDER GIVEN TERMINAL CONDITIONS

For the same receiver voltage, equation (**19**) shows that I_r may be increased in the same ratio that Z is decreased without affecting e_g, since the hyperbolic terms are substantially constant for a given frequency and length of line for both single- and multiple-conductor circuits. It follows, therefore, that when resistance is small, or when the ratio of resistance to reactance is the same for both circuits, the power which can be transmitted at a specified voltage drop, receiver voltage, and power factor, varies inversely as the respective reactances of the single- and multiple-conductor circuits.

For unequal ratios of resistance to reactance, this simple relation will hold only approximately, but in any case it may be used to advantage in estimating the power which can be transmitted over a multiple-conductor circuit. It may also be used to determine approximately the spacings required with a proposed arrangement of conductors to deliver a given amount of power under specified terminal conditions.

For example: Suppose it is known that 150,000 kw. can be delivered over a certain 230-kv. single-conductor line with given terminal voltages and receiver-end power factor. The reactance of the line is 0.8 ohms per mile.

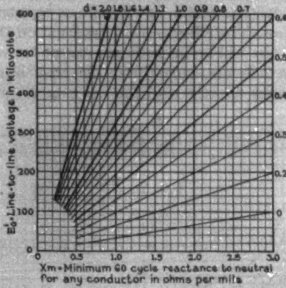

FIG. 9—E_0', FIRST APPROXIMATION OF CORONA STARTING VOLTAGE AS AFFECTED BY DIAMETER OF CONDUCTOR AND MINIMUM REACTANCE PER MILE AT 60 CYCLES

d = diameter of conductor in inches

$$E_0 = E_0'/D, \text{ where } D = 1 + k\frac{d}{m}$$

It is required to transmit 210,000 kw. at substantially the same terminal conditions over a circuit of the same length having two conductors per phase, vertically arranged.

To increase the power in the ratio 210/150 the reactance must be reduced to approximately $0.8 \times 150/210 = 0.571$ ohms per mile. With two conductors per phase the average reactance per conductor, x_c, will be $2 \times 0.571 = 1.143$ ohms per mile. From Table II $x_k = 0.056$, and from (**18**) $x_m = x_c - x_k = 1.087$ ohms per mile. From Fig. 9 the diameter to avoid corona at 230 kv. must be greater than 0.66 inches, how much greater depending upon the ratio d/m.

Fig. 1 shows all possible combinations of the ratios S/d and S/m which will give the required reactance. The choice of spacings between phases and between conductors of the same phase is limited by mechanical considerations; consequently, it may not be possible to use spacings which would give the best results electrically. The following combinations of S, m and d are among those which will give a reactance of approximately 0.571 ohms per mile, and have a corona starting voltage above 230 kv., the operating voltage.

S-ft.	m-ft.	d-inches	S/d	S/m
15	1.25	0.728	20.6	12.00
20	2.00	0.806	24.8	10.00
25	3.00	0.855	29.3	8.3

STABILITY

The methods now in use for determining the stability limits of systems composed of single-conductor circuits may be applied with equal rigor to systems containing one or more multiple-conductor circuits.

A multiple-conductor circuit can be designed to carry more power than a single-conductor circuit of the same length and operating voltage. Accordingly, fewer multiple- than single-conductor circuits are required to transmit a given amount of power from a generating plant to its load center under specified terminal conditions.

The relative stability of a proposed system with multiple- or single-conductor circuits would depend upon whether the operating conditions are to be the same for the two schemes with all lines in service or in the emergency conditions of one line out of service. When the two systems are designed to operate under the same terminal conditions with all lines in service, the total reactance and capacity susceptance between line terminals will be substantially the same whether multiple- or single-conductor circuits are employed. Consequently, under normal operating conditions the steady-state power limit and margin of stability would be the same for either arrangement. With a line out of service, the steady-state power limit with multiple-conductor circuits would be less than with single-conductor circuits. Should the systems be designed to operate under the same terminal conditions during emergency conditions, the relative steady-state stability with multiple-conductor circuits would be increased.

A fault on a conductor of a multiple-conductor circuit will be a less severe shock to the system than one on a conductor of a single-conductor circuit. But after the fault has been cleared, the loss of a multiple-conductor circuit would reduce the synchronizing torque between generator and load to a greater extent than the loss of a single-conductor circuit. The stability of the two systems under transients conditions would depend upon the location and duration of the fault, the number of conductors involved and the relative amounts of power carried by a multiple- and a single-conductor circuit.

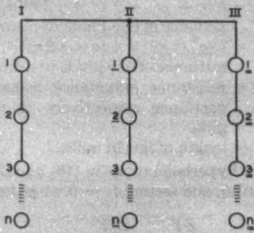

FIG. 10—THREE-PHASE MULTIPLE-CONDUCTOR CIRCUIT HAVING *n* CONDUCTORS PER PHASE

ACKNOWLEDGMENT

The author wishes to express her appreciation of the assistance given by Mr. R. N. Slinger and Mr. M. A. DeFerranti in the preparation of the curves.

Appendix A

INDUCTANCE AND 60-CYCLE REACTANCE OF MULTIPLE-CONDUCTOR CIRCUITS

When a three-phase multiple-conductor transmission line is completely transposed so that each conductor occupies each of the tower positions, or its equivalent, for equal distances, the phases being rotated in cyclic order, the total inductance to neutral of any conductor will be the sum of the inductances in each position.

Let

n = number of conductors per phase.
l = total length of each conductor.
$l/3n$ = length of conductor in each position.
I = current in phase A.
I/n = current in one conductor of phase A.

$$\frac{I}{n}\left(-\frac{1}{2}-j\frac{\sqrt{3}}{2}\right)=\frac{I}{n}a^2$$

= current in one conductor of phase B

$$\frac{I}{n}\left(-\frac{1}{2}+j\frac{\sqrt{3}}{2}\right)=\frac{I}{n}a$$

= current in one conductor of phase C

The phase positions on the tower will be designated by I, II, and III, and the conductor positions in the phase positions by 1, 2 . . . n, *1, 2* . . . *n*, and **1, 2** . . . **n** respectively. Fig. 10.*

Starting with phase A in position I, the conductor of phase A which first occupies the position I-1 will in turn occupy each of the $3n$ positions for equal distances, $l/3n$.

For sine waves of current of frequency f, the total inductive voltage drop in any conductor will be the sum of the voltage drops in the conductor for the $3n$ positions and may be expressed in terms of self-inductance, L_1, and mutual inductance, M.

With the conductor in position I-1

$$V_{\mathrm{I}-1}=2\pi f\left[\frac{\mathrm{I}}{n}(L_1+M_{12}+\ .\ .\ .+M_{1n})\right.$$
$$+\frac{\mathrm{I}}{n}a^2(M_{\mathit{11}}+M_{\mathit{12}}+\ .\ .\ .+M_{\mathit{1n}})$$
$$\left.+\frac{\mathrm{I}}{n}a(M_{\mathbf{11}}+M_{\mathbf{12}}+\ .\ .\ .+M_{\mathbf{1n}})\right]\quad\textbf{(1a)}$$
